Now let us look at the conditions which bring about these different results. In Mysore we have the sea to the west then a comparatively narrow strip of flat country, and then the imposing Ghauts rearing their mighty heads abruptly over the plain and their limbs lying carelessly down towards another plain but at a far different elevation. This plain is the wonderful table-land of Mysore which stretches for some hundreds of miles of open *maidan*. On my arrival here fresh

* A sea-weed? It grows plentifully on coconut palms. —ED.

from the sappy verdant island of Ceylon, my eye wearied as I journeyed across this bare country. That was in October, and how much more would I have felt the contrast a few months latter on in the pucka drought. Coffee planters have discovered that their "zone" lies just at the junction of the rain-compelling Ghaut region and the dry open country beyond. Thus they secure a proportion of benefits derived from each.

Now let us look at Ceylon. You will of course be quite aware of the fact that towards the west wherever the land rises to any elevation we find the south-west monsoon emptying itself freely. Let us look along the hilly frontier. Begin from the north, and we get the Laggala or Knuckles range. Straight up the railway pass sweep the winds of the S. W. monsoon which branch off on either side of the hot valley of Dumbara bestowing that burden on the steep hill-sides on either side. Thus Medamahanuwara, Rangala, Knuckles, and especially Kelebokka, because it lies nearest the south-west—all got a large proportion of wind and rain, while over the mountains the wind increases and the wet decreases as you leave Laggala and approach Nitre Cave. Away beyond to the north and east lies the lowcountry where rain is not plentiful. Here we approach the line which must be considered hereafter. I may state that this line may be drawn across the map due south from a little east of Medamahanuwara, cutting Wilson's Bungalow and a point between Haldummulla resthouse and that of Belihuloya, and so on south. This is the drier zone of the island. It can be *seen* from Medamahanuwara or Badulla; it can be felt by anyone journeying from Nuwara Eliya to Wilson's Bungalow, and it can be seen clearly either from Haputale on the one side or Rakwana on the other. I must return to the N. W. of the hill country. I pointed out where the S. W. monsoon strikes the northern coffee districts. Now I proceed in a direct line to Ratnapura, or Adam's Peak. Here is a bold frontier like the Ghauts facing the lowcountry towards Colombo, but, unlike this country, there is not an open flat plain behind but a series of undulating hills including such prominent peaks as Sentry-box, Peacock and the culminating majestic ranges of Pidurutalagala. Thus the coffee-covered country where lie the districts of Ambagamuwa, Dikoya, Maskeliya and Dimbula gets a severe share of the rain-laden clouds which strike the ranges of Adam's Peak and Kirigalpotta. This frontier is beautifully seen from the Nahaveena range in Rakwana. Now comes in the supplementary range of Rakwana which forms a break-weather to Uva, the latter being further favoured by the dry zone mentioned above. Do figures bear out these? Let us see.

Madulkele	...	115	in. per annum.
Rangala	...	101	,, ,,
Dolosbage	...	200	,, ,,
Ambagamuwa	...	199	,, ,,
Dikoya	...	146	,, ,,
Maskeliya	...	137	,, ,,
Dimbula	...	103	,, ,,

These all lie on the frontiers, save Dimbula and Rangala, which are favoured in the former by its lying nearer the dry zone, and, in the latter, by the influence of Dumbara. Then come those districts affected by the giant Piduru. Maturata, not properly kept—but probably high like Dimbula near the dry zone but not within its influence.

Kotmale	...	150	in. per annum.
Nuwara Eliya	...	102	,, ,,

Now I will take the supplementary frontier—the Gongala range. This range begins at the other side of Ratnapura from Adam's Peak and runs S.E. till it crosses the dry zone and stops below Gongala Peak. It includes the following districts:—

Rakwana (facing N.E.)	131in.	per annum
Kukulu Korale (facing S.W.)	167 ,,	,,
Morawak Korale (facing S.W.)	111 ,,	,,

Then come the drier districts:—

Haldummulla (Wiharagala)	88 ,,	,,
Kandapola (near Nuwara Eliya but within the dry zone)	90 ,,	,,
Badulla	90 ,,	,,
Walapane (Dunugala dry zone)	83 ,,	,,
Dumbara (peculiarly situated by itself)	57 ,,	,,

Another section, which includes the five last districts comes under the influence of N. E. rains that come down the Bay of Bengal. This influence culminates with the Hewa Eliya range where we have 116½ inches. The Nitre Cave in the north makes up for its being robbed of a good deal of the S. W. by getting a large share of the N. E. rains which are checked on the summit of the range by the dry weather towards Colombo. Monaragala remains and shows it is within the dry zone by its rainfall, viz., 88 inches. From the P. W. D. returns you will find that on the west and south the rains in the lowcountry are far heavier than on the north and east. Galle on the South getting 85 inches and Trincomalee in the east 61; and Jaffna in the north 40, while Kalutara in the west registers 102 inches.

So much for Ceylon rainfall. Now where do we find coffee to flourish the best? Before leaf-disease the Knuckles range did splendidly in days gone by, but the plantations did not lie high up the ranges as a rule but extended only to where the soil was good. Ambagamuwa was a failure on account of bad climate and bad heavy stiff soil. The three sisters, Dimbula, Dikoya and Maskeliya, had the misfortune to have been exposed in early youth to certain plagues such as leaf-disease, speculators, grub, moneyed youngsters and "high" cultivation. They have not swamped Brazil yet. The range of older districts between the Hantane and the Piduru ranges did very well as the S. W. was more humble and played out before it reached them; so they had a very even climate except on their borders all round. Uva stands preeminently above them all in soil and climate as it is within the dry zone and has not suffered from heavy lasting salt-laden rains, but experiences straight-down N. E. plumpers which swell its average but bring down lots of nitrogen.

Kukulu Korale and Morawak Korale are the very reverse of this. They get salty fierce storms fresh form the briny, and nothing grows there save mortgages and frogs.* Rakwana gets oftener warmed by the sun as it rises over distant Uva, but the wind is a caution. There are three places in Ceylon where a thin man on a narrow horse would have a chance over all.

1. A corner of the road at Lauderdale estate Rakwana.
2. A corner of the road below Hakgala for Nuwara Eliya.
3. A corner of the road in Nitre Cave near Corbet's Gap.

Now I would advise all coffee in the wetter districts to be abandoned and tea planted except those where wind is great.† The balance of good land in these can be made to pay under tea, In the drier climates start growing *shade* if it is not there already, and put in Coorg coffee if cacao won't do better. But do not expect to grow fruit to pay for a prolonged period if there be undue exposure either to

Severe wet,
Severe wind, or
Severe drought.

* Our correspondent forgets tea.—ED. C. O.

† Tea can stand a good deal of wind.—ED. C. O.

Take the happy medium leaving to the last, and have shade if you want fruit.

Every coffee planter with the droughts in view must in Mysore attend to shade. In Dumbara, shade has been found beneficial for a long time; and it was only comparatively lately, that a man thrilled his neighbours by using the razor (I mean the axe) all over the place because his cacaos where hanging fire, then blaming the shade when he should have blamed the soil. Now I am curious to know if THIS is the estate afflicted by discase. That 's it! Outrage nature in tea as you have done in coffee, cinchona, and cacao, and then howl out about occult and mysterious diseases. H. V. is not felt here, and apparently where shade and shelter were attended to and the soil was good this nocturnal fly did not do appreciable damage to cacao in Ceylon.

Coffee is an aged steed and a cripple. *Cinchona* makes the running for a short time, but pulls up foundered. *Cacao* is a good horse, but far too small. *Rubber* is an out and out sell. TEA was a dark horse, but will stay and win in the end. *Don't* burst her! Keep the pace within herself, and she 'll come in at the end at a canter, hands down. Here coffee is past and present and future. Coffee to the coffee planters, nothing else save in a small scale for an amusement. Also cardamoms but few have the chance to do much there.

Now that you have got your railway or so much of it, it does n't seem to please you. The more you get may be the less pleased you'll be! If you can make your railway pay by tea you will do a lot and it 's all before you. Go ahead and "pruv" it. Don't go on inventing new diseases with scientific jaw-breaking nomenclature, but work quietly, sensibly and *naturally*. These schemes of Messrs. Smith, Elphinstone and Sinclair are not wholesome symptoms. They try to force the inexorable course of certain laws. I see nothing that Government could be expected even to listen to in these schemes. A free passage to and slight assistance on landing at a foreign shore where valuable tropical experience is needed might be more feasible, but young men are generally preferred as they are more easily got rid of if unsuitable.

In Ceylon where your climate is always moist, the question of silos, or the principle of ensilage, can have but little interest to you. In India, however, where the existence of cattle is a struggle in the dry weather, rough, cheap, effective silos are a most useful means of increasing and keeping up the supply of manure instead of letting the three-quarter-famished herds scour the surrounding maidans without a bellyful by evening. Sir Herbert Macpherson deserves the thanks of all Indian agriculturists for his efforts, and *successful* efforts, in instituting cheap silos among the natives. A rough hole, any size you like, is made; a fire is burnt inside; the sides are smeared with cow-dung and clay which form a suitable cement; the sides of the hole slope towards each other; rough wet grass is cut and thrown in and trampled down; stones and earth are heaped on the top; and then a smooth roof is made over the whole, the circumference of which extends beyond that of the hole, and the ground sloped off on all sides beyond. A planter thus would have plenty of good food for his manure-makers during the long drought.

I often think how useful the "gorraga" would be to you. When the monsoon is in full force in Ceylon pipes and pyjamas are the thing in the bungalow, nakedness and rice in the lines. Work is at a standstill, and it really looks inhuman to him to turn out coolies in weather not fit for a dog. But here the natives have a light contrivance not unlike the corracle of the ancient Briton when it is represented in pictures as being carried on the head. This "gorraga" is made of two frameworks of bamboo or "watte" with large leaves of a kind of reed placed between after being first boiled to bring out a gummy juice that renders the leaves adhesive. The frameworks are then tied all round with cane and you have a very effective covering. Though I know you can't reproduce it I annex a sketch. * * *

This allows of work being carried on in all weathers and the European is protected by waterproofs more than is the case in Ceylon. I remember the coolies considered a durai was a V. A. or "Colombo durai" if he went about in a waterproof. The P. D. appeared occasionally in his rain-coat while the S. D. scorned even an umbrella. The climate of Ceylon must be good because I had ten monsoons of it and I did not fancy waterproofs or umbrellas.

The Sinhalese have a makeshift of a talipot-leaf but they have to hold it with one hand while the "gorragas" rest on the head and back. The legs are apt to get wet, but the dusky ladies are not troubled with excessive modesty and the men have less clothes than a Highlander below the waist.

Now I have sent you a long rambling letter. I still have a warm corner in my heart for Ceylon, and the *Observer* is welcomed and prized before "home" papers. In fact, it is the chief "home" paper to me.

The Coorg men are trying to cut down rates of wages to labourers. One man thinks it a good idea *because* the people are well off. Is it because it wouldn't be so hard on the poor coolies, or is it an erroneous idea that it is easier to cut down pay when there is more attraction at home for the workman? As prosperity waxes or wanes in the ryot's village so the supply of labour to Europeans follows suit and therefore it is a time of famine and hardship in the villages; that is the planters' opportunity. The question lies in a nut-shell. Is the demand less than the supply? If so, down goes the pay and the people have to "lump it."

ABERDONENSIS.

P.S.—Here 's my cure for "fly" in cacao:—

In Dumbara on poor ridges, *the axe*; hew it down, &c.
In Dumbara on southern aspects, shelter and shade.
In Dumbara on northern aspects, shade only.
This applies to Matale also.
In Kurunegala in good land, shade and shelter.
Everywhere else in the Central Province and Kalutara I would recommend the fire stick.

COFFEE IN BRAZIL.

DEAR SIR,—In the *Tropical Agriculturist* for 1881-82 (page 844) there is an article on "Coffee Dying Out from Disease in Brazil," in which I read as follows:—"The disease is of so fatal a nature that in 14 years once productive coffee orchards had become a thing of the past in a district whence the infection was *rapidly spreading*." From this cause, as well as from a certain policy of the Brazilian Government, and low prices, it is inferred that "over-production will be checked." But against this (and in the same article) I read:—"Year after year the area of coffee has steadily grown. * * * The country lacks *no single element* which can contribute to the success of a great industry," (coffee) with the exception of those named above. Further on I read that the "consuming markets of the world are actually glutted, and yet the area of production is being steadily increased."

All this was, and *is*, very interesting to Ceylon coffee-planters. It goes without saying that this note of warning, sounded nearly three years ago, pointed to the true cause of the *present* depression in the coffee market. Add to this the increasing production of the minor coffee-producing countries of Central America. A friend in London sends me the following letter:—"The following is the extract from my brother's lette

dated San José, Costa Rica, 8th January 1884 :—'We are just beginning the coffee crop which is abundant, and if the weather continues fine, as it is at present, it will be a great benefit to the country, as it is the largest crop for many years.'" And, admitting that Ceylon has now very few "elements which can contribute to the success of coffee,' the question of its continued expensive cultivation here is well-worthy of careful consideration. Has anything *more* been heard of this disease in Brazil since the above was written three years ago? Much of the Ceylon coffee has succumbed within the period of "fourteen years" since first attacked by leaf-disease, though much also still remains vigorous; but is still attacked by leaf-disease in proportion as it bears crop. Cinchona and neglected cultivation largely aided to kill the coffee already gone out, but the true struggle with the disease is between it and the coffee through which cinchona has never been planted. How long will this last? In the case of insolvent proprietors its duration will be short: but with owners who do not expect too much from it, its life may be indefinitely prolonged, or until the rest of the property is paying from other products. *Then*, I fancy, it also will be allowed to disappear, for Ceylon now occupies this position in the world: it cannot (even under more favorable conditions than exist at present) compete, as a coffee-producing country, with those other countries which "glut the markets of the world," and in which "no single element is lacking which can contribute to success." Whereas, on the other hand, it is becoming daily more certain that, as a tea-producing country, *it* lacks no element of success, but possesses these elements in greater abundance than any other country.

In consequence of this, the majority of estates in Ceylon are of much greater value this year than they were last year, in proportion as they have planted tea, and are well-placed as to climate and carriage, and prepared for its manufacture. The disease in Brazil will probably lag far behind in the race between it and the "growing area" of new fields. At all events, the present generation of Ceylon planters are not likely to reap any indirect benefit from this cause, even if their own remnant of coffee would hold out so long. Coffee-planting in Ceylon is a thing of the past: from its ashes the country will soon rise into a new life of prosperity when two men will be required for every one it supported in its best days. But how many of the old planters will share this new life whose breath are tea, cacao, cinchona and scraps of coffee? K.

CORROSIVE SUBLIMATE AND WHITE-ANTS.

Colombo, 30th July 1884.

DEAR SIR,—Will the application of corrosive sublimate prevent white-ants from destroying the beams and rafters of a house which they have already commenced to attack? If so, how should it be used? A reply to the above, or any other effectual remedy for white-ants, from your good self or any of your correspondents, will very greatly oblige.—Yours faithfully, HOUSEHOLDER.

[We regret that this letter should have been overlooked. If corrosive sublimate (dissolved) is brushed on, so as to come in contact with the ants, it will certainly destroy them.—ED.]

PLANTING IN COORG.

High Field Estate, Madenad, Coorg, 8th Aug. 1884.

DEAR SIR,—We are now in the full swing of the monsoon, and up to date have registered 94 inches this district. Coffee here having proved a failure, planters are busy in supplying up with cinchona. On one group of estates in this district 7½ lacs of Robusta and Ledger plants have been planted between every coffee-tree with the hoped-for result that in the course of a few years magnificent fortunes will be reaped out of what Dod Bora calls the Quinine Gidda. There are also one or two small clearings of verde which are very promising.

Great reductions have been going on all over Coorg consequent on the low state of the market, no less than 14 superintendents' services having been dispensed with and writers on pay not exceeding R50 a month being taken on in their places: whether this method of reduction will pay remains to be seen, my own opinion being it will not, as Eurasians and natives, however good they may appear to be when the manager's eyes are on them, care for nothing but drawing their pay, while an European superintendent generally has his employers' interest at heart.

I have been trying the kola nut here. Though having been in the ground over five months, they are only just commencing to germinate. Perhaps the elevation (3,650 feet) is too high.

Indiarubber (Ceará) seems to find little favour. What, wait 10 years? Where shall I be then? &c., &c. This was the same cry they made about cinchona, and now these men would give their ears to have those years back again.

A neighbour of mine seems to be very successful with unfiled seeds by placing them in horse-dung: they seem to germinate very freely.

Regarding tea, that it grows and grows well here has been proved, but want of capital keeps this product in the background.—I am, dear sirs, yours faithfully, SPENCER MARSLAND.

A BIG POD.

Koslanda, 10th August 1884.

DEAR SIR,—By today's post I send you, in a match-box, the seed-pod of a tree I found near here. Can you tell me what the name of the tree is of which it is the seed, and whether it is of any particular use?

You will see there is a dark sticky matter round the seeds which I am told the natives sometimes eat. What I send you today is only a small part of the seed-pod: the original pod when I took it off the tree was quite 2 ft. long.

The tree from which I took the seed is a large one, with leaves and flowers very much like the laburnum. The flower is of the same colour as the laburnum (yellow), but larger and very sweet scented. —I am, yours faithfully, G. C.

[The box has not reached us, but we have no difficulty from the description in recognizing the *Cassia fistula*, which on our visit to Haputale last year we found blazing with golden blossoms below Koslanda and again in approaching Belihuloya from Haldummulla. The natives use not only the pods but the bark as medicine, and, from their inveterate habit of barking the trees, it is difficult to preserve the specimens of *Cassia fistula*, now scattered about Colombo. There are fine specimens in several gardens in Colombo. One grown from seed which we brought from Batticaloa in 1861 was a few months ago simply a mass of gold. This and the Madagascar tree (*Poinciana regia*) form splendid contrasts of rich green, scarlet, orange and bright yellow. Gamble, in his "Manual of Indian Timbers," writes of this tree, which is widely distributed in India and Ceylon, from sea-level to 4,000 feet :—"The wood is very durable, but rarely of sufficiently large size for timber. It makes excellent posts, and is good for carts, agricultural implements, and rice-pounders. The pulp of the pods is a strong purgative; the bark is used in dyeing and

tanning, and the gum as an astringent. It is a very handsome tree, having long pendulous racemes of bright yellow flowers, and a long, straight, cylindrical, indehiscent pod, often one and two feet long. It is often cultivated for ornament." This "Indian laburnum," with bougainvillea climbing up its stem, ought to be in every garden in Colombo and other towns.—ED.]

AN ENEMY OF TEA.

Preston, Agrapatana, August 14th 1884.

DEAR SIR,—I have just recently planted some 36 acres of tea in a clearing with coffee, and cinchona, and the young plants are being attacked by a small "spider" insect; its color is *black* with *white spots on the back*. It perforates the leaves as well as eating them. I should feel much obliged by your giving me any information or remedy.—Yours faithfully, CHARLES A SETON.

[We regret that we cannot identify the insect from the above description. We shall be glad to receive a specimen.—ED.]

GINGER CULTIVATION 1 ACRE.

Land		$10·00
Trenching		40·00
Clearing jungle		25·00
Pegging		6·50
Planting		10·00
Price of plants		25·00
Keeping clean		6·00

Total two years' expenditure ...		$348·00
By sale of two years' crop, say 8,000 lb. dry ginger at 15c per lb ...		$1,200·00
Seen expenditure		348·00
Profit for two years ...		$852·00

Nawalapitiya, 12th August 1884.

DEAR SIR,—If you require further information, I can let you or any other person have it. I am sorry that you rather throw cold water on the cultivation of arrowroot, but I only hope some person will make a trial of both it and ginger. This estimate is expressed in $ not R. as the last letter of mine.—Yours faithfully, W. M. P.

PRESERVING FRUITS, VEGETABLES, ETC.

Office of World's Industrial and Cotton Centennial Exposition, Commissioners for Florida.

BRONSON, FLA., May 31st, 1884.—I am in receipt of inquiries by letter from parties desiring to prepare ripe and unripe fruits and vegetables for the New Orleans World's Exposition, and I hand you the receipt used by Hon. A. J. McWhirter, of Tennessee, and Prof. Dabney, of North Carolina. They tell me that fruits put up in this way will keep for years and look perfectly natural. Please publish it, and I hope your readers will preserve the receipt, so they will have it at hand to guide them in the preparation of their exhibits for the World's Exposition, to be held in New Orleans next December, 1884:

RECEIPT.

1. For preserving strawberries, raspberries, blackberries, currants, gooseberries, plums and cherries, when thoroughly ripe, use proof alcohol.

2. For peaches, apples, pears, plums, currants and gooseberries, when not thoroughly ripe, use one part water and two parts proof alcohol.

3. After the fruit stands in the alcohol three or four days, pour off and add fresh alcohol, as above directed, until all the coloring matter has been extracted; then put the specimens for permanent use in one part alcohol and one part water (pure, clear water.)

4. The proportions for peaches, apples and pears will answer for all kinds of vegetables.

5. Alcohol once used and discolored can be filtered and used on other fruits or vegetables, or for permanent specimens.—*Florida Despatch.*

LONDON TEA LETTER.

(From the *Indigo and Tea Planters' Gazette.*)

At the Health Exhibition there is a plant (a seedling about 18 inches high) of the Maté or Paraguay tea. I was much struck with the perfect resemblance of this specimen to a good Assam jat tea plant, and I would challenge any planter to pick it out of 50 such plants. The size, shape, colour, serrated edges, gloss of the leaves are identical to all appearances, the wood and bark are also undistinguishable at a glance from that of a pure Assam plant. Yet the Maté is called a holly! *Ilex Paraguayensis*, or Brazilian holly, growing in Paraguay and Brazil. Its active ingredient, *Paraguaine*, formerly supposed to be a distinct principle, has, from further researches into its composition, been discovered to be identical with theine and caffeine—the alkaloids of tea and coffee. Unless the appearance of this "holly" changes very much as it grows older, it is difficult to understand how it can have earned that name. Can chemists have made a mistake, in calling *Paraguaine* a distinct principle from *theine*? and is this holly a sister of the indigenous Assam plant after all? The Maté, as prepared by the Paraguayans, judging from the samples shown at the Health Exhibition, is simply a pounded mixture of sun-dried leaves and twigs of a light green colour in which the portions of twigs are clearly distinguishable. Other samples of Maté I have seen have consisted simply of shiny, angular, flat hard fractions of leaves alone, free of all stalk. The Mate is usually soaked in a gourd from which it is imbibed, and samples of these gourds are also shown, and I believe are for sale. There has been no withering, rolling, fermenting or firing in the preparation of Maté, as is evident at a glance. It would be very interesting, if not profitable, to obtain sufficient leaves to make a handful of tea, as we know it, from Maté plants; but I doubt if there are sufficient plants in this country to admit of the experiment being tried. I mean to make enquiries.

PERIPATETIC PLANTER.

MANUFACTURE OF DATE SUGAR IN BENGAL.—The supply of coarse brown sugar or molasses in Bengal is mainly derived not from the cane, but from the date tree, and the date plantations have, during the last fifty or sixty years, enormously increased over several well-known districts—Jessore, Burdwan, Baraset, and Nuddea. The trees are planted in rows or clumps, and are not grown for fruit, as in Arabia or Beluchistan; but the tree becomes profitable after seven years' growth, and may continue to yield a return for thirty or forty. In the month of October the ryots are seen ascending their date trees, and making incisions on alternate sides, in alternate years, on the lowest branch of the feathery tuft at the top. An earthen pot is placed under each incision, and when the cold nights begin, the liquid flows slowly into the pot beneath, whence it is removed in the morning. The colder and stiller be the weather the greater the flow of juice. Rainy weather, such as now and then interrupts the enjoyable climate of the cold season, stops the flow of juice for a time, but the process goes on, with few intervals, between November and March. The juice is boiled down and clarified by means of a coarse weed that grows in almost every tank, and the whole cultivation is highly remunerative. The spaces between the trees in a date plantation are turned to account otherwise, for early rice and for the second crop of mustard. Many substantial ryots own 400 to 500, and even 1,000 of these trees, and the traffic in goor or treacle adds life and animation to the interior of Bengal.—*Mercury*

CAROB BEANS.

The saccharine pods of the Ceratonia siliqua have become an article of considerable importance as a food for domestic cattle, and the export is now large from many of the Mediterranean countries. From Candia or Crete the shipments have been said to reach 180,000 tons annually, from Cyprus 10,000 tons are exported, and from the districts of Tarragona in Spain as much.

In several of the countries where the tree is largely grown, horses and stable cattle are almost exclusively fed upon the pods. About 6 lb. a day are given of the crushed pods, raw or boiled, with or without chaff. The meat of sheep and pigs is also greatly improved in flavour by this pod, the fattening properties being twice that of oil-cake; hence Carob beans form a chief ingredient in most of the artificially prepared cattle foods. They contain about 66 per cent of sugar and gum. The tree is grown in Italy, Portugal, and Spain, the south of France, and most of the islands of the Mediterranean. It has been also carried to South America and India. The produce is annually increasing in Cyprus. The tree grows readily in moist soils, and not requiring much moisture or care, its cultivation gives little trouble; however, although the tree grows and thrives without much moisture, the yield of fruit is affected during dry seasons, the quantity being less, and the quality inferior.

In Crete the trees in the eastern part of the island produce a much finer pod than elsewhere, which realise 1s. a cwt. more than those in the centre of the island. The produce always finds a ready market at Constantinople and the ports of the Black Sea. These pods, in some of the countries where it is abundant, are a great resource to the poorer classes, who eat them in large quantities, particularly in Lent Containing a good proportion of sugar, they are very nourishing and satisfying when fresh, besides being cheap, and having the virtue of keeping well. As met with here, however, they are hard and leathery, and not very attractive.

As an economic plant already it is strange that no attempts have been made by improved culture to transform the pod into a savoury edible fruit.

In Portugal the pods are known under the name Algarobas, and in Austria as Johannes' Bread. It has the reputation of being the food on which St. John fed in the wilderness; but this is questionable, as it was most probably the insect locusts, which are parched and eaten to this day in parts of Africa. In Vienna Caroh beans are sold at all the fruit stalls in the streets; and they are even sold in many sweet shops in London and elsewhere, being purchased by children. In Sicily a spirit and a syrup are made from the sweet pods; it has a flavour not disagreeable, and resembling in taste the fruit. Aromatised liqueurs have also been made from it. In Egypt a mucilaginous refreshing beverage is made from the pods, and they steep in it the fruits of the Balanites ægyptica.—*Gardeners' Chronicle.*

THE WEST INDIA FRUIT TRADE.

The abundance and cheapness of our British fruits, owing to the prolonged fine weather, give an interest to a consideration of the commerce in those tropical fruits which in the places of growth would be gladly exchanged for some of the more common European fruits, such as Apples and Pears, Strawberries, Raspberries, and Cherries. The supply of Oranges and Lemons has also been very abundant and cheap in our markets this year. A few statistics of the trade in tropical fruits of the West Indies, which is mainly carried on with North America, may prove of interest at the present time. New York and Boston are the chief centres for the sale of tropical fruits. The figures cited are chiefly those for 1882.

The trade in West Indian Oranges proved unsatisfactory and unprofitable, 23,000,000 were received from Jamaica out of a total of 31,000,000, and one-third of the quantity perished on the voyage. The other islands from which supplies of Oranges came were Cuba, Bahamas, Dominica, Trinidad, and Porto Rico. Florida is fast becoming a competitor in Oranges, having supplied 500,000 boxes and barrels, and in another decade it will be able to supply the whole United States with an abundance of fine Oranges.

The import of Pine-apples into New York was over 2,500,000, principally from the Bahamas and Jamaica, with a few from Cuba and Curaçoa. The average loss of the fruit on the voyage was 20 per cent. Nearly two million Pine-apples are annually canned or packed at the factories of one firm at Eleuthera and Harbour Island, about three-fourths of which find a market in New York, and the residue in Europe. The annual production of Pine-apples in the State of Florida is gradually on the increase, a quarter of a million of fine Pines of superior quality having been received in New York in 1882.

The Banana trade is an important one in the principal United States ports. It is the fruit of the Sweet Plantain (Musa sapientum). In California and Florida M. Cavendishii, a dwarf and more robust species is chiefly grown, the yield of fruit being profuse (as much as 200 or 300 fruits in a spike), and the flavour excellent. The delicate fruit of the eastern species, M. sinuarum, never reaches this country; they attain a length of 1 to 2 feet. The longer voyage from the West Indies or Madeira seldom allows Bananas to arrive in good condition in the London market, nor is this fruit so generally appreciated here as in America, where it is a common dessert fruit.

The importation of Bananas at New York was double that of 1881, but a striking offset was offered to this increase in the very notable decrease in Oranges, probably the most commonly used of all the imported fruits. Nearly 1,000,000 bunches of Bananas were received; of the above over 150,000 bunches perished on the voyage—a loss of 16 per cent. The imports are principally from Aspinwall and Jamaica. There are also direct imports at Boston of about 250,000 bunches. The price received in Jamaica is from £5 to £10 per 100 bunches, the former representing the lowest price given in dull seasons, and the latter the highest when fruit was most in demand.

All the Bananas imported into the United States come from the Isthmus of Panama and the West Indies. The different varieties are called Aspinwall, Baracoa, and Jamaica, after the places from which they are shipped. The Aspinwall Bananas are large and yellow, and termed silver-skinned. The Baracoa, so named from the port in Cuba at which they are shipped, are red-skinned. The Jamaica Bananas are yellow and smaller. The Aspinwall fruit is hardy, and can bear handling and heat or cold better than the other two kinds. The Baracoa fruit, which comes from the south-east end of Cuba, is by some people thought to be superior to the Aspinwall and Jamaica kinds, as it is more luscious. The wholesale price last year was 2s. 6d. to 2s. 9d. per bunch.

The Jamaica Bananas have improved in quality lately, and fetched 2s. 8d. to 4s. a bunch. Steamers have now been put on, which make the passage from Jamaica in eight and a half days against fifteen or twenty days by the ordinary sailing schooners. The loss on the voyage, which was formerly from 10 to 15 per cent, has been almost overcome, and better fruit is brought in as the steamer can take a cargo of nearly ripe fruit.

The Aspinwall Bananas come to market throughout the year. Those from Jamaica and Baracoa reach the American markets from March 1 to about August 15. In Jamaica when a sucker is planted it only comes up single and bears but one bunch of fruit, while in Aspinwall a sucker comes up with several shoots, and these bear in succession one after another. In Aspinwall also the fruit comes to maturity in half the time it does in Jamaica or Cuba. During the last six years the value of the annual exports of Bananas from Port Antonio, Jamaica, has more than doubled. In 1877 the value of those shipped was only £7,747, in the two following years it averaged £18,000; last year it reached £40,000. Considerable quantities are also shipped from the ports of Lucia, Montego Bay, St. Ann's, Port Marie, and Kingston.

The Banana is an annual, the fruit coming to maturity about a year from the time that the shoot is planted, the stem of the plant then attaining a height of 8 or 10 feet and perhaps 36 inches in girth. There are a good many Plantain walks in the island varying in size from 25,000 to 200,000 trees, but they are for the most part cultivated by the small settlers in the different parishes, and prove a source of great profit to them. The method of cultivation is simple. The land is cleared by the aid of a primitive and ponderous hoe, a hole is dug in which

is placed a "sucker," and Nature is left to do the rest. Unless the season be one of exceeding drought, the plant is certain to grow and to bring forth its fruit in from nine to twelve months. In well ordered plantations the trees are usually planted from 12 to 15 feet apart in the form of squares. The Bananas are taken to market, not unfrequently a distance of 20 miles, by means of clumsy, springless drays and carts upon which thirty or forty bunches are indiscriminately placed with some attempt at wrapping them in the dried leaves of the plant, and are chafed and scarred by the wheels of the vehicle and the weight of the driver, who generally makes a comfortable perch for himself on the top of the whole. These defects do not present themselves until the fruit has been in the ship's hold some days, when they result in unsightly dark patches.

The total value of the green fruit imported into New York in 1882 was given as follows in the Custom House returns in dollars:—

Oranges and Lemons	770,601
Grapes	77,278
Pine-apples	20,522
Bananas	82,323
Miscellaneous	12,000
Cocoa-nuts	353,502
	1,316,226

Or, in round numbers, £261,000. The miscellaneous fruit in the last item comprised Limes, Shaddocks, Mangoes, Grape fruit, Plantains, Sapodillas, Avocado Pears, Guavas, and several other varieties not specified.—P. L. S.—*Gardeners' Chronicle.*

A COMFORT TO SUFFERERS FROM FEVER.

Under the above title the "Sempervirens" of Feb. 9th bespeaks an account from the "Pharmaceutisch Weekblad" of 3rd of February.

The comfort in question results from the fact that the price of Sulphate of quinine has fallen so enormously (within 2 years to 50 p. c.) and the store of the raw material (Cinchona bark) in London has increased to an alarming extent.

These facts cannot be gainsaid. The supplies of the article from South America and Asia have increased awfully of late years. If 30 years ago it was dreaded that the supply might once come to fail, and this dread induced the English, French and Dutch Governments to make experiments for the transplanting and acclimatizing of the Cinchona tree in their respective colonies, these experiments were crowned with such eminent success, that it begins now to be feared with reason, that the market may become overstocked. Besides this, the primeval woods of South America prove to possess still greater abundance than could ever have been surmised. New sources were discovered, and in sundry parts of the home of the Cinchona, the work was also grappled with, and people began to apply themselves to a regular culture.

So the supplies from America have not only increased, but the British Colonies produce at present already collectively, as much cinchona bark as was for years received only from America. The use of the precious medicine has undeniably increased considerably, and we may assume that there will be a constant progression; but nobody uses cinchona bark or the alkaloids prepared from it, for his own pleasure, and though progressing civilization and cares for hygeine force up the demand for the medicament, it can no longer be doubted that the balance must be already considered as destroyed, that the production far exceeds the demand.

In London there lies about 5 millions Kilogr. of cinchona bark in stock, sufficient for the wants of a whole year,* and the supplies continue, nay even increase yearly, were it only by the increasing age of the now young plantations in Asia.

Were we now to proclaim, like the "Pharm. Weekblad" that there is nothing in the preceding statements discouraging for our excellent cinchona plantations and their enterprising owners in Java, and if we perfectly agree with the prediction of the "Indische Opmerker," d. 27 Dec. 1883" that any competition can be borne in Java, provided care be taken to apply exclusively to the planting of trees rich in quinine, we advise due caution in appreciating these statements, and feel convinced, that, for the first few years, every idea ought to be given up of establishing new cinchona concerns.

As an example of the vast scale on which the cinchona culture is practised in Java, the condition of the government concerns is adduced. They number a total of 3,300,000 plants. Ten years ago the amount was 2,000,000.

Let us add, however, that in Java there are about sixty private concerns where cinchona is cultivated, among these above thirty that apply themselves exclusively to this culture. Most of them are relatively young, but together they number—the figure is not exactly known—certainly 10 or 12 times more plants than the government concerns, and if these can bring into the market in 1881 250 or 300 thousand Kilogr. of this product, a production which goes on increasing every year, because every year new gardens of greater extent, and at the same time—to a certain limit—of richer percentage, can be brought under exploitation, then it is positive that within five years the production of the government concerns will offer but a small fraction of the total produce of Java, while this produce is not yet one-fourth of what is yielded by Ceylon alone.

If then, at present, the wants are so much exceeded by the produce, in half a decennium there may be a glut, for it is not imaginable that the consumption will, in any degree, increase in the same proportion.

Then there ever remain in view the dangers* of artificial quinine preparatioos, and the finding of effective substitutes for the cinchona bark. It must be acknowledged that such an event becomes less a cause of anxiety to the cinchona planters as the cinchona bark can be offered cheaper. But this cheapness has its limits. Before the cinchona trees can be brought to yield anything like a good material, a period of 6 or 8 years is required. A cinchona plantation, therefore, calls for considerable capital, and hence rent and interest. When the harvesting time comes, and so realization begins, then maintenance, harvest, package, despatch, etc., entail expenses that cannot be defrayed as soon as the prices of the material fall below certain limits.

It is very natural that then the best chances remain on the side of those planters who can offer the *richest* material, and that therefore it is, very rightly, urgently recommended and insisted upon, as a *sina qua non*, that only the very richest sorts of trees should be cultivated. It must not, however, be imagined that our mighty rivals, the English, would ignore this principle, nor abuse ourselves with the idea that the cultivation of exclusively rich quinine-bearing trees is absolutely in one's power, at least as long, as is now still the case, as we are and remain dependent on government concerns, and a few private persons, for the dispensing of seed.

Seeds may be obtained from parent trees that are positively rich in quinine, which yet produce a whole roll of varieties. And one may offer and receive in good faith seeds of undoubted excellence, which after a few years may lead to disappointment, on subjecting the products to a chemical analysis.

It has been thought a sufficient guarantee against degeneration to propagate plants whose high value was ascertained by analysis, and as yet there is no positive reason to doubt it; but they who rear cinchona will do well to consult history.

No culture in India was ever so regularly and amply described, from the very beginning, as that of the Cinchona. The official reports were regularly printed, and if you will take the trouble to consult them from 1864 up to now, you will see that it was always thought, by virtue of the analyses, that the best available qualities were propagated, and yet the practical results were constantly disappointing, not always answering to the promises held forth by the results of the analyses.

It is also true that gradually many improvements have been introduced into the method of analysis, but it will always remain a fact, that we have not nature under our control, have not yet even discovered what it is, in most

* Especially considering the great stock of alkaloid in the factories.

* Especially with regard to the great provision of alkaloid in the factories.

cases, that promotes the formation of alkaloids in the living bark, and so nobody can positively affirm "from these seeds you will rear trees, that will furnish bark of so much percentage of quinine."

And however favourably one may think of the constant value of slips, grafts, etc., even very early disappointments are recorded in this respect, which we are now apt to ascribe to the imperfect analysis of the time, but which we cannot consider altogether as impossible. Besides this, few planters will be sufficiently lucky to propagate, by exclusively artificial means, and it will have to be proved in a proximate future, whether the growth and vigour of the artificially reared cinchona plants are and remain as favourable under all circumstances.

Courageous and hopeful planters in India reckon upon America being unable to bear up against the competition, considering the great expenses of exploitation and transport here. This is specially a question of means of communication, and history teaches us how these are affected and improved according to requirements. To save costs of transport it has been proposed to work out the material in India to the alkaloid; but if need presses, is it likely that such a resource would be neglected in America?

Ceylon is not decided as a rival, because the plantations die away there prematurely. But in Ceylon they continue planting, and skilful planters have there too brought to light: "why this premature ripening" is a lamentable fact, and by what means it is to be combated.

We do not wish to discourage our present cinchona planters, but we wish to warn them against exaggerated representations and dangerous illusions, as we are absolutely of opinion that presistence in the way of extravagance adopted of late years, will inevitably lead to the ruin of all. New concerns are nonsense, al long as the yearly consumption of the article does not increase immensely more than has been calculated hitherto.—VAN GORKOM.—*Indian Mercury.*

COFFEE AND SUGAR IN DEMERARA.

From a paper on "The River Berbice and its Tributaries," by Alexander Winter, in *Timehri*, Vol II., Pt. II, we quote as follows:—

* * * *

Berbice has suffered much socially from the transfer of the seat of government to Demerary, and by the system of centralisation which has followed this, as well as from the removal of the troops and from the cessation of the coffee cultivation; yet the town of New Amsterdam has gone on increasing in size and number of inhabitants. The population by the census of 1881 was 8,386, and the amount of shipping that cleared at the Port last year was 26,685 tons.

The river opposite the town is broad but shallow. On the west bank was formerly a continuous line of estates for some fifteen miles up. Now, excepting plantation *Blairmont*, there is not a single estate in cultivation on that side of the river. On the town side about two miles up is a fine sugar estate called *Providence*. This is the only sugar estate in the country that remains in the possession of the same family that owned it at the time of emancipation in 1834.

About three miles further, at Plantation *Bellevue* (happily so named), the river takes a bend and a fine reach opens up, giving a somewhat lake-like character to the scenery. This reach is called in the Dutch grants, the "Groote marri-paam," meaning probably the great estuary, or sea reach.

Near the upper end of the Groote marri-paam on the east bank is Plantation *Highbury*, a fine sugar estate that once belonged to the "Berbice Association." The Berbice Association occupied in this colony very much the same position as the East India Company did in Hindoostan. Although owning allegiance to the Sovereignity of the States General in Holland, the members of the association were the virtual proprietors of all the country, and had the government of it. They sold out lots of land to private individuals who were willing to cultivate them and establish estates. These lots or grants were all carefully measured by land surveyors, and diagrams of them were deposited in the Registrar's Office, where they are still to be seen; but the association retained certain portions themselves and established what were called "model estates." These were not measured off and no boundaries fixed, as all the ungranted land belonged to the association.

These estates are valled "Society's ground," or "Society's Plantations" in the Dutch charts of the colony; and in Downer's map of Berbice they are marked as "Colony Estates." At the time of the capture of the colony by the English, there were four of these estates in cultivation in the hands of the association; and it was specially agreed that they should be treated as private and not as government property. In the Act of Capitulation of the Colony of Berbice in September 1803, it was stipulated in Article 2 that "The Plantations, Lands, "Manufactories, Workshops, Slaves, Effects and Possessions of the Berbice Association of whatever nature "shall be considered as Private Property in the same "manner as is agreed to by the Capitulation with General "Whyte in May, 1796."

The estates reserved to the association under this article were Dageraad, St. Jan, Daukbaurheid and Sandvoort. The association carried on the cultivation of these estates until the year 1818, when they sold them to English proprietors.

From the earliest days of the occupation of Guiana by the Dutch, there had been some English settlers, but these were much increased in number after 1814, in which year the colonies of Demerary, Essequibo and Berbice were finally ceded to Great Britain by the Government of the Netherlands. Soon after many estates were bought by the merchants of London, Liverpool, Bristol and Glasgow; and in 1818 estates in Berbice seem to have attracted the attention of British capitalists to a considerable extent, and the Dutch Berbice Association availed themselves of it to dispose of their estates. The purchasers were Messrs. D. C. Cameron, Henry Davidson, and Æneas Barkly. The directors of the association were represented on this occasion by their attorney, Mr. Thomson Hankey of Mincing Lane, whose power of attorney is recorded in the Registrar's Office of Berbice.*

The following is the entry in the Highbury books of this purchase:—

"The Colony Estates, November 1818.
"Plantation Account Proper Dr.
"To Thomson Hankey, 99.
"For the purchase of the following Plantations from "him in August last, viz., Pln. Sandvoort, Pln. "Daukbarheid, and Dageraad with all and every "thing to the same belonging together, with 682 "slaves, names and particulars as per Inventory "filed—£66,000 @ *f*12 ... ... *f*792,000

"Thomson Hankey, 99, Dr.
"To Davidsons, Barkly & Co.
"For this sum paid him on signing of contract for "part payment of purchase of said estates— "£22,000 @ *f*12 ... ... *f*264,000

The partners in this purchase divided their interest in it thus:—Mr. D. C. Cameron, joined by his friend Mr. John Cameron (*Glenevis*), took *Sandvoort*, which was a large coffee estate in Canje. This they divided in two, and made one-half of it a sugar estate, which they called *Lochaber*, after the head quarters of the Camerons in Scotland. The remaining three estates were retained by the other two partners: *St. Jan* and *Daukbaurheid* were united and called *Highbury* after Mr. Barkly's place Highbury Grove, near London; *Dageraad* was continued in cultivation for some time, but eventually was made over to government as an asylum for lepers.

Both *Dageraad* and *Highbury* were worked by water power. The water from the river was admitted by a large brick sluice some six or eight feet wide, which was shut at high water, to retain the water till half ebb-tide, when it was loosed out at a narrow sluice about two feet wide, thus forming a mill-race in which the wheel worked which drove the cane mill. One inconvenience of this system was that the machinery could only be worked when the tide suited, whether by day or night.

* A carefully compiled index to the records of this office has been lately made. It was commenced by the late Registrar, Mr. A. B. Stewart, and completed by the gentlemen now in charge, Mr. O'Meara and Mr. Jas. Walls.

Highbury was the first estate in Berbice that employed coolies from India. It soon became evident that the negroes after emancipation would not work as they had before, and that if British Guiana were to continue a sugar-producing colony, additional labourers must be introduced from elsewhere.

So Messrs. Davidsons, Barkly & Co. joined by Mr. Moss, of Liverpool, and some others, sent to India for some of the surplus population of that teeming country; and in 1838 the ship "Whitby" arrived from Calcutta with the first lot of coolies! They were a very fine set of people and did remarkably well at *Highbury*; and at the end of their indenture they returned to India carrying large sums of money with them. Thus was commenced that system of Indian immigration which has saved this colony from abandonment and bids fair to establish a labour supply on such a footing as will ensure to the present sugar estates something like an adequate return for the enormous amount of capital, skill and energy that has been expended on them. Capital has followed the supply of labour, and science is following capital. But success is only now setting in, after an arduous struggle of over forty years, during which most of the proprietors of former days have disappeared.

By the disposal of their estates the "Berbice Associatioo" ceased to have any interest in the colony, which soon became thoroughly British. A few coffee estates remained in the hands of merchants in Holland up to the time of emancipation; but for some years past not a single estate in Berbice has been owned by a Dutchman, and the time seems to have arrived for revising the system of Dutch laws guaranteed to the former owners of the colony by the Articles of Capitulation. It surely is unreasonable that Englishmen in a British colony, living under the reign of a limited monarch, should be tied down to a foreign law of inheritance forced on them eighty years ago by a Dutch Republic which no longer exists.

Towards the head of Groote marri-paam the river has a winding course of some ten miles, and here the water is deep. Here there were once ten or twelve coffee estates and two sugar estates, all now out of cultivation. One of the former, plantation *Bestendighied*, belonged to an enterprising Dutch planter named Timmers, who, at the time of emancipation, thinking as many did then, that the colony was about to enter on a course of prosperity under a happier system, extended his operations at *Bestendighied* by adding a saw-mill to his coffee machinery, and getting out a steam engine to work the whole. The river Abary flows parallel to the Berbice, at no great distance from its left bank. Mr. Timmers connected his estate with the Abary by extending his middle-walk canal a couple of miles through the savannah into the Abary. At this point the whole country is an extensive swamp with a foot or two of water over the surface, but a few miles higher up the lands rises, and there is a high reef on which is a forest of bullet-trees; and Mr. Timmers proposed cutting timber there, with the assistance of some Warrau Indians who were then living on the spot, and bringing it down the Abary, and up his canal to the *Bestendighied* buildings, where it would be sawn into plank by his newly erected steam engine, which would thus be kept usefully employed when there was no coffee crop going on. It was a well conceived plan, and for sometime things looked promising, but, alas! the want of labour, which in this colony generally defeats every project, caused it to fail. Coffee cultivation ceased to be profitable because the laborers would not pick the crop, hard times set in, and poor "Polyglot Timmers" had to pass through the insolvent's court!*

A few miles above *Bestendighied* the river makes a bold turn to the eastward, and consequently vessels sailing up meet the wind right a head, and instead of running before the wind, they have to beat against it, and their progress is much retarded; hence this turn in the river has got the name of "Humbug Point." Beyond this, a fine stretch opens up, running nearly due south for about eight miles. This is called in the Dutch grants the "Klein marri-paam," or little sea reach. There was once an unbroken line of coffee estates along this on the east bank. There are now only two estates in cultivation, both in sugar. These are plantations *Mara* and *Ma Retraite*, now the property of the Colonial Company, but formerly owned by Messrs. George and James Laing, the leading merchants of Berbice, and the most enterprising and energetic of our colonists. Emancipation took place in August 1834. This was followed by the apprenticeship system, during which the negroes were still under some control, and had to continue on their estates and work certain regulated hours a day, for which they received money wages. This was intended to accustom the newly emancipated to habits of steady industry and to prepare them for unlimited freedom. Estates throve under the system; the seasons happened to be good, and the price of sugar ran up very high. This gave a great impulse to speculation, the Dutch sold out their coffee estates to the more enterprising English who put them in sugar. The Messrs. Laing bought plantation *Mara*, which was then in coffee, put it in canes, and established a fine sugar estate. The apprenticeship system according to the emancipation act was to continue six years, but four only had elapsed when it was prematurely terminated, and the negroes made entirely free, and left to their own devices. From this time the planters' troubles commenced in earnest; prices fell, labour was scarce and only to be had at a high rate. Hard indeed was the struggle; and many had to succumb. The Messrs. Laing suffered severely, for they had embarked largely, having besides *Mara*, become interested in *Ma Retraite*, *Friends*, *Enfield*, *Smythfield* and *Albion*. Mr. James Laing published a touching memorial on the subject,* addressed to Lord Grey, showing that though starting under the most favorable auspices, the investments of himself and partner had resulted in a loss of £197,000 sterling, incurred from the 1st August 1836 to 31st December 1847. He winds up his indignant protest in these words, "In such case no choice will be left to the memorialist "than to abandon the cultivation of his estates, and sub- "mit to their realisation at whatever sacrifice, in behalf "of his creditors. But, he will deem it only due to him- "self, and to his family, and creditors to appeal to the "justice of Parliament and the people of England for "redress and compensation for losses which have been al- "together occasioned by the Legislation and acts of the "British Government."

It was probably such cases as this, and there were many of them, that at last startled the Colonial Office into believing the truth of the reports of the state of the West Indies, and of the necessity of at once coming to their relief by sanctioning the importation of laborers from the East, as otherwise the cultivation of sugar would cease, the educated classes would abandon the colonies, and the manumission of the negroes prove a dead failure. Earl Grey tells us as much in his book "The Colonial Policy of Lord John Russell's Government." He says (page 63.):—

"This prosperity, and the welfare of all classes of the "inhabitants of these colonies, depend upon their being en- "abled to continue to advantage the cultivation of sugar, "not merely because this branch of industry constitutes "their chief source of wealth, but because, if it were to "cease, there would no longer be any motive for the resid- "ence of the European inhabitants in a climate uncongenial "to their constitution, while it is certain that they could "not be withdrawn without giving an almost fatal check "to the civilisation of the Negroes."

Beyond *Mara* there is no estate in cultivation, and in passing up the river we leave sugar estates and their cares behind us.

TROPICAL FRUITS:—BANANAS.

BY J. H. WRIGHT.

Desiring to call to notice the different fruits as they present themselves to us in season, it is appropriate to speak upon the banana now, as this is one of the most important months of the year to the banana dealer.

Probably no fruit of the tropics is at present commanding more commercial attention in our Northern markets,

* This sobriquet he got from his habit of jumbling up so many languages in his talk, Dutch, English, French and Creole Dutch.

* A similar memorial was also sent in by the late R. M. Jones, Esq., of Pln. *Houston*, Demerary. A beautiful marble monument to the memory of Mr. George Laing has been erected in the Court House, New Amsterdam.

nor whose introduction has been attended with more difficulties than has the banana. Millions of dollars have been expended in developing the trade and placing the fruit before the public; lives have been lost in defending its interests, and the armies of Central America have been called out to quell riots caused by collisions of rival companies in their endeavors to obtain a foothold, or share, of the banana trade of Central America. There a monopoly had obtained a strong hold, preventing by every means in their power rival companies from securing any fruit from what they looked upon as their territory (Aspinwall.) Before speaking of some of the above difficulties, it may be well to speak of the early introduction of bananas into our Northern markets.

As stated in a former paper the first bananas, about thirty bunches, were brought to New York in 1804 by Captain John N. Chester, of the schooner "Reynard." On the voyage to this country the Captain fell in with three French frigates in company on one of which was the late Jerome Bonaparte, then on his way to Baltimore to marry Miss Paterson. On learning the object of his visit to this country the Captain presented the distinguished visitor with a bunch of bananas, some pineapples and plantains, which were thankfully received. The balance of the bananas, on their arrival in New York were purchased by a fruit dealer in the old "Fly Market," at the foot of Maiden lane. This tropical production meeting with public favor other small shipments were made until 1830, when the demand became so great that Mr. John Pearsall, an enterprizing fruit merchant, seeing its increasing popularity, chartered a schooner to transport the first full cargo of red bananas ever brought to New York from Baracoa. It consisted of 1,500 bunches and required a number of days to dispose of what at that early day seemed an immense quantity.

Some of the giant strides made in the banana trade since that date may be appreciated, when I tell you that Mr. Theodore Pearsall a member of the firm of Gomez & Pearsall, and a nephew of the famous pioneer spoken of above, has sold during the last three months between one and two hundred thousand bunches of red bananas from Baracoa.

Last year the importation of red bananas from Baracoa, consisted of 14 steamers and 134 sailing vessels, bringing nearly half a million of bunches, while this season from March 1st to present time, May 26th, 1884, three hundred thousand bunches of red bananas have left that port. Until quite recently sailing vessels have been exclusively used to transport bananas from Baracoa, it requiring under favorable circumstances, about 10 days to run a vessel from there to this port; but owing to the uncertainty of the winds and the waves it often occurred that 12, 14 and sometimes 20 days were required, which resulted in an almost total loss of the fruit, or at least a dead ripe cargo, which had to be sold at a great sacrifice, to licensed vendors, street stands and cheap trade of the city, as none so ripe could be used for shipping out of town. The importers seeing the need of more rapid means of transportation for the banana than the uncertain sailing vessel chartered a number of steamships, and finding they could reach New York from Baracoa in from four to five days it enabled them to ship fruit of a superior quality without fear or rotting on the voyage, thus establishing the fact that the steamship is the only reliable mode of transportation for the banana, and the day is not far distant when the sailing vessel as a banana carrier will be a thing of the past, and steamships alone will be used for that purpose. Not satisfied alone with this advanced step in the transportation of the banana on the water, attention was turned towards improving the mode of carrying them from the plantation to the sea shore, where they were to be loaded in the vessel or steamer. Until quite recently it was the custom of the native darkey to carry the bunch of banana on his or her head or strap upon the back and sides of a donkey, mule or cow if they were wealthy enough to own one. It is a common sight in the tropics to see a family of six or more darkies coming a distance of several miles, each with a bunch of bananas balanced upon their heads, the good wife having to carry the largest bunch, and each of the children the next largest bunches, the lazy husband selecting the smallest bunch for himself, and I am told it is a good husband who will carry one at all. One of these small darkey children, I am told, will carry a bunch upon his head for miles, that would make us stagger to put upon our shoulders. Larger growers of bananas, and these who make it strictly a business, transport most of their bananas upon the backs and sides of mules, of which they own large droves. So well drilled are these animals that when loaded they will start off following the "bell" mule, as the most faithful one was called, having a strap about her neck with a cow bell attached. So they wind their way down the mountain side to the sea-shore. The mule, as most of you doubtless have learned, is not altogether a reliable beast, and taking the idea into his head that he is tired, will avail himself of the first opportunity to lie down in the road, much of the discomfort of the driver and detriment of the fruit, which is either crushed or covered with mud and dirt, causing black and unsightly streaks upon it which very much lessen its market value. A somewhat better idea of a banana caravan may be formed by relating a description of one, as given me by Mr. John Marsh, an enterprizing fruit merchant of this city, and a gentleman of keen observation and wide experience in foreign travel. He says:—"In my recent visit to Baracoa, having taken about a four-mile climb, up the mountain side, my guide said, 'let us now take our lunch,' and following him into a coconut walk, protected from the rays of a tropical sun, we seated ourselves for our repast, when my guide suddenly said: 'Hark! there is the banana train.' We could just hear the tinkle of the mule bell, and looking up the side of the mountain, we saw, on the path 200 feet above, the approaching mules and ponies-laden with the red bananas eight bunches to each beast, three bunches on each side and two on the top, all strapped on with a grass girth. Let us count; sixty mules, ponies, and cows, with eight bunches each, 480 bunches in all with but one driver to the train. Slowly they jog along, about four miles an hour, down the mountain sides until they reach the sea coast. Some of the trains come twenty miles with their fruits, and you may look with surprise when I tell you that one pony can take back, with ease, the proceeds of the whole train in the hampers on his back, as in most cases the fruit is paid for in supplies of provisions at the store of the agent. I have seen cargo after cargo loaded, and not a dollar in money exchange hands. What would a Long Island farmer say if he had to unload at our market, on the same terms? The rapidly increasing demand for bananas from Baracoa required a more modern means of conveying the fruit from the plantation to sea coast. With Spanish capital and American ingenuity, an inclined plane or trestle railroad was designed last year in New York, where it was made in sections and sent to Baracoa, and put up at a town called Yumena, about thirty-five miles east of Baracoa, that being the largest banana growing district, but Baracoa being the nearest available harbour for vessels. The fruit is brought to it by small boats and lighters by the aid of steam tug. It takes the fruit from about sixteen acres of good, fertile land to load one steamer with 10,000 bunches. A schooner carrying from one to two thousand bunches is chartered for the round trip for about $1,000, allowing 15 days to load and unload. It requires about six men to run a banana schooner—a captain, mate, three seamen and a cook. Yumera is reached from Baracoa by a shallow stream, through which boats of only light draught can go. Along the coast from Baracoa to Yumera is a range of rocky hills or bluffs, (resembling our Palisades on the Hudson) down which winding roads to the shore, have been cut, and these roads are used for banana transportation, as well as other travel from the villages above. The introduction of the inclined railroad from the foot of the bluff to the summit, a distance of several thousand feet, has shortened the route so greatly that much labor and time is saved, and the fruit is also better protected. The cars carry down the incline about twenty-five bunches of bananas at a cost of ten cents per bunch. The incline being a double track railway, one car goes down loaded with fruit while the other is going up with freight or passengers to the village of Sabana. So popular and successful an enterprise did this elevator prove last year that it paid a handsome dividend of over 40 per cent, on the

investment. The original cost of this incline, I am told, was about $7,000, but has been recently sold for $14,000 to a stock company, of which the shippers of bananas to the firm of Gomez and Pearsall of New York are large shareholders. I understand it is expected that another and similar incline is about to be started near the present one, which will make another step forward in advancing the facilities for banana transportation.

* * * * * * * * * *

Among all known plants that produce a wholesome and agreeable food, the banana offers the greatest return for the least labor. Life being so easily sustained by its bounty in those favored regions, where it flourishes, one of the chief incentives to exertion is removed and people are content to sit down in idleness, knowing that when hungry a never-failing supply of bread hangs over them ready to be plucked and eaten, for which reason it is a debatable question whether the banana and plantain are not to be considered a curse rather than a blessing to mankind, and as encouraging inactivity, instead of industry and progress, for so long as a native darkey of the tropics has a handful of rice and a piece of tobacco the size of his thumb, you can hardly induce him to work at any price; having but few artificial wants to supply, he has no need for money, a coffee sack furnishing him with a year's wearing apparel.

Let us see what uses have been found for the fruit, leaf and stem of the banana. As an article of food the banana is very nutritious and wholesome, furnishing the staple article of diet for many families in the tropics. It is eaten cooked or raw. It is said that many Mexican tribes subsist almost entirely upon its flour or paste, which is made by cutting the banana into strips, dried and pounded into a paste. In Jamaica a very superior farina is made from it. It is sliced when green, dried in the sun, afterwards heated into a powder and sifted. It is used largely among the negroes, who feed their babies with it, and speak highly of its nutritious properties. When made into "Pap, or Johnny cake," is excellent food for the most delicate stomach. Some idea of the nutritive qualities of the banana may be obtained from Humboldt's analysis of the banana. He tells us that he finds it to contain forty times as much nutriment as the potatoe; he also says that one acre of bananas will produce as much actual food as forty acres of potatoes, and comparing it to wheat, he says that a surface bearing wheat enough to feed one man, will, when planted with bananas, feed twenty-five men.

The young shoots are cooked as greens and said to be much relished by those who have eaten them. In India the natives serve it up in many ways. A favorite dish is prepared by taking a number of thoroughly ripe plantains or bananas; after removing the skin, the fruit is mashed and mixed with fine wheaten flour, a sufficient quantity of sugar and a little pounded cardamom seed: it is then mixed with milk and water, formed into small cakes of any desired shape, and when fried in olive oil is said to be highly nutritious and palatable. The rind of the banana in India is greedily eaten by all manner of live stock, when mixed with straw, oil cake and other ingredients, and is looked upon as valuable stock food. As an article of food for table dessert, it is used largely by many Southern hotels and families. Bananas also make a delicious addition to ice cream, sliced thin and stirred in just as the cream is beginning to freeze, or served with it without being frozen; to have them nice they should be cut up and set on ice about an hour before serving. On shipboard it is used largely as a dessert, being made into pies, puddings, short-cake and fritters; in fact they are now advertised in our city restaurant bill of fares. They are also dried in slices for export resembling in appearance a dried herring, but to the present time have not met with favor in New York. From the banana an excellent starch, wine, flour, vinegar, farina and sugar is also procured.

From the young leaf an excellent healing quality is obtained for a cut or wound.

From the stalk and leaf is obtained a beautiful silken fibre from which can be made a fine dress goods, said to resemble closely the Irish poplin, and when the suitable machinery is made for decorticating the fibre in its entirety, there will no doubt be wonderful developments in imitations of silk goods. An excellent paper pulp can also be made from the stalk. In Jamaica much interest is manifested by some of its enterprising citizens, as well as the Jamaica Institute, regarding fibre, and a few months ago Mr. George Roe, a native of Jamaica, whom I had the pleasure of entertaining, told me that for years this important branch of industry has occupied a great deal of his time and attention, but as he never found anyone willing or sufficiently interested in the matter to give an attentive ear to the opinions and views he had on the subject, and not having the necessary capital to carry on the experiment, he was obliged to abandon the enterprise that he firmly believes will at no distant day command large commercial attention, and that the thousands of acres of land bearing millions of tons of banana fibre now allowed to rot and decay will be utilized for fibre, from which will be made beautiful fabrics, as well as paper pulp, &c. At present the natives make use of the fibre of the banana stalk and leaf obtained in a rude way for making door and sleeping mats, mule saddles, rope, cordage, &c.

Mr. Roe told us how desirous the Jamaica Institute was to encourage the utilization of the large quantities of bark and fibre growing so luxuriantly in a wild as well as cultivated state, throughout the entire island, and which have hitherto been suffered to fall to waste and decay. The interest taken in this matter by the Institute is forcibly evinced by the very liberal offer of a premium of £10 for the best essay on the subject, as well as a further award of £50 for 100 weight of fibre produced by machinery invented in that country. These offers were publicly made known to the natives and inhabitants generally through the columns of several newspapers, but up to the present time, Mr. Roe informs us, but little consideration has been paid to this liberal offer. The sap of the banana stock may be used as writing fluid or indelible dye, which no series of washing will remove, and is made by pressing a quantity of juice from the stack, which, when boiled in an iron vessel, is converted into tannate of iron, and, with sulphate of iron added, produces a beautiful ink or dye.

Having found food in its sprouts, starch, sugar, wine-vinegar and flour in its fruit, medicinal qualities in its leaf, ink and dye stuffs in its sap, and from its stalk a fibre from which choice fabrics can be made, I feel confident in claiming for the banana, viewing it botanically aesthetically and gastronomically, that it has no peer.—*American Grocer.*

ORANGE SOUFFLE'—Peel and slice six oranges, put in a glass dish a layer of oranges, then one of sugar, and so on until all the oranges are used, and let stand two hours; make a soft-boiled custard of yolks of two eggs, a pint of milk, sugar to taste, with grating of orange peel for flavor, and pour over the oranges when cool enough not to break the dish. Beat the whites of the eggs to a stiff froth, sweeten to taste and pour over the top. Serve cold.—*Rural Californian.*

ROOT-PRUNING TREES.—When fruit trees have a tendency to luxuriant branches, and a meagre crop of fruit, root-pruning is advisable. The operation consists in digging a circular trench at a distance of from three to six feet from the tree, according to its size and growth, cutting away all the roots that may be encountered, afterward returning the soil. The best season of the year for this pruning is just before the completion of the annual growth in the fall, so that a check will have the effect to lessen the flow of sap, and promote the formation of flower buds instead of wood buds.—*Rural Californian.*

THE GUM of a species of *Grevillea* acclimatized in Algeria has recently been examined by M. G. Fleury (*Journ. de Pharm.*, p. 479). The gum is of a yellowish or reddish brown colour, and horny consistence. In water it swells, diffuses slowly, and produces a white emulsion of a very persistent character, which easily passes through the filter. It is found by M. Fleury to consist of a gum approaching in character that of gum arabic, and a fluid reddish transparent resin without odour soluble in alcohol. This resin is also soluble in alkalies, in methylic alcohol and bisulphide of carbon; it possesses feebly acid properties and forms about 5 to 6 per cent of the gum. The separated gum does not actually dissolve in water, but if a little potash, lime, or carbonate of potash be added to it when swelled up by water, solution takes place immediately, the solution becoming gelatinous upon the addition of a ferric salt. An alkaline solution becomes darker and more viscous if exposed to the air.—*Pharmaceutical Journal.*

MARKET RATES FOR OLD AND NEW PRODUCTS.

(From Lewis & Peat's London Price Current, July 31st, 1884.)

IMPORTED FROM MALABAR COAST, COCHIN, CEYLON, MADRAS, &c.	QUALITY.	QUOTATIONS.
BEES' WAX, White	Slightly softish to good hard bright	£7 a £8 10s
Yellow	Do. drossy & dark ditto	£5 10s a £6
CINCHONA BARK-Crown	Renewed	1s 6d a 4s

THE COCKCHAFER-BEETLE GRUBS AND THEIR DEVASTATIONS.

It seems a great pity, that, with Mr. McLachlan's opinions on questions referred to him in regard to grubs and their ravages on Ceylon coffee estates, the documents submitted to him, especially the numbered points, I., II., III., &c., to which his attention was directed, were not published simultaneously. In the absence of Mr. Christie's report and the details given by Mr. Braine and others, a degree of obscurity surrounds some of the details; but what is clear is, that, however much light naturalists may throw on the life history of the insects (and their name seems to be "Legion," because they are many), which devour the feeding rootlets of grass, bushes and trees, men of science are as helpless as the most ordinary planter or farmer in providing an effectual remedy. In this respect, the history of black or brown bug which closed the pores and sucked the juices of the coffee tree; the black or brown grub which "ringed" and destroyed millions of young coffee plants in the field; of the white or yellow-white grub which devours the feeding rootlets of the grown coffee bushes; and, finally, of the fungus (worst pest of all) which saps the very life of the plant by exhausting the juices of its foliage—is uniformly the same. There *are* means, no doubt, which on a limited scale have been found effectual for the destruction of each of the pests named, but it is the vast profusion of the insects or fungi and their almost universal diffusion (bug and grub coming and going, but the fungus being chronic,) which render the application of remedies impracticable. There is a very valuable American work on insects injurious to vegetation, in which a large amount of information regarding the *Melolonthidæ* or "May bugs" is collected, and one of the statements made is that in view of the occasional terrible destructiveness of the cockchafers, "the Society of Arts in London, during many years, held forth a premium, for the best account of this insect, and the means of checking its ravages, *but without having produced one successful claimant.*" This does not look encouraging, and it is simply tantalizing, in view of the almost entire absence of insectivorous birds from the coffee estates of Ceylon, to be advised to encourage rooks (the very crows of Ceylon give the grubs in coffee a wide berth), gulls, jays, shrikes, &c. It is of no practical use to us to be told how the rooks and gulls follow the plough at home and gorge themselves with the upturned grubs. From the fact that our cultivated plant is perennial and from the steep features of most coffee estates, ploughing in coffee estates is impossible. Pigs, if penned over successive portions of a coffee field, would soon rout out the grubs, but we suppose the reason why this remedy has not been tried, has been the certain conviction that in routing out the grubs the porcine diggers would root out the coffee bushes. If we could procure pigs "learned" enough to make and observe the distinction, the pig remedy would be a real one. We suppose the very promising remedy of compelling the grubs to come to the surface by spreading gunny bags or other coverings over the ground was found too expensive? Careful forking of the soil (our substitute for ploughing), if carefully conducted and so as not to add to the destruction of the tender rootlets, was no doubt one of the best possible modes of up-turning the grubs from their subterranean abodes and destroying them, while the soil received culture which opened it to the genial influences of sun and air and rai But this very process, no doubt, facilitated the deposit of fresh stocks of eggs by the females of the cockchafer beetles. The remedy apparently suggested by some planters of beating the ground into such a state of hardness that the beetle could not penetrate it, would be an injurious, if not a fatal expedient, and as for the advocates of weeds on estates and those who hold that grubs do not attack healthy roots of healthy plants, the accumulated evidence places them entirely out of court. It is unhappily too true that as in ringing young coffee plants the brown grub chose the plants of most luxuriant growth, so the big, white grub of "the patana cockchafer" prefers the healthiest and most succulent rootlets, whether of grass or trees, for his food. We must, in many cases, go beyond our own limited experience. Judging from what we have seen in Ceylon, we should lay down the proposition that white ants never attack living and healthy tissues. But it is beyond dispute that in India, the tea planters have to remove dead timber from their land, lest the white ants from the decaying wood should attack and destroy their tea plants. We have not heard of white ants attacking tea in Ceylon, and happily, grubs, except in rare and isolated cases, do not seem to affect the tea plant. While cinchonas planted on patanas were savagely attacked by grubs, tea plants put out in like condition were left scatheless. This is a very important fact as regards our new enterprize. It is curious that, as stated by Mr. Christie, that in the Maskeliya district the damage done by grub should first have attracted attention in 1877, the year of culminating prosperity for coffee and every other interest in Ceylon. In that year, however, *Hemileia vastatrix* had been at work for eleven years, and in the older districts grub and the damage inflicted by it had been too well known many years previously to 1877. Maskeliya seems, however, to have a chafer (appropriate name) of its own.

Mr. Christie reported that trees reduced to living skeletons by the ravages of grub, were particularly liable to the attacks of leaf-disease. There can be no doubt, on the other hand, that the debility induced by continued attacks of leaf-disease rendered the trees less able to resist or recover from the attacks of grubs. Unhappily evils of this kind act and react on each other, as primary and secondary diseases do on the human frame. We are surprised to find Dr. King quoted as saying that the grubs, which a couple of years ago devastated the Darjiling Botanic Garden, were the larvæ of an unknown beetle. There can be no doubt, we should think, they were cockchafer grubs. We, in Ceylon have not got the marked cold and hot seasons which Dr. King refers to as regulating the downward and upward movements of the grubs, but of course, here as elsewhere, there are seasons when the grubs come close to the surface and when they can best be dealt with. In Europe the grub after existing for three years in the soil in the larva state, changes into a beetle, but the now winged insect is in no hurry about its resurrection, but remains in a semi-dormant state near the surface for the fourth year. This is the stage at which specially the beetles should, if possible, be disposed of. But Mr. Haldane is inclined to think that the influence of our tropical climate shortens the subterranean stages of the life of the insect, and the decision of this question Mr. McLachlan relegates to observers in Ceylon. It is quite evident from the number of the Ceylon specimens sent being declared new, unknown or doubtful, that a wide field for investigation is open to entomologists in Ceylon We hope Mr. Christie's report and Mr. Braine's note, if not already published (?), will be given to the world. Our wealth (?) in beetle life seems perfectly marvellous. We should like specially to receive information as to

the behaviour of the cockchafer grubs on those patanas which are believed to be their original homes. In Europe the cockchafer grubs so eat away the roots of grass on swards and lawns, that the stems and the surface soil in which they grew, could be rolled up, as if separated from the earth below by a lawn-mower or similar machine. We have never heard of the insects doing anything like this in Ceylon, nor indeed have we ever heard of patana grasses being seriously injured by grubs, although their presence and propensities become at once apparent when foreign plants, such as cinchonas are placed on the patanas. We know that when Mr. Elphinstone propounded the theory now endorsed by Sir William Gregory, that to the non-burning of patanas was largely attributable the prevalence of grubs, a well-known planter in Dimbula, possessor of large expanses of patana, repudiated the idea. We should like to hear him on the whole question, including the prospects of tea culture on patana lands. It is important to know that although some species of beetles, which haunt coffee blossoms are not harmful, any more than bees are, the cockchafers and the allied species of beetles, should be destroyed wherever found, not only because of the destructive grubs they propagate, but because the winged insects themselves damage the flowers of coffee and other plants by destroying the pistils and stamens and so preventing fructification. How far has observation here confirmed this position of Mr. McLachlan's. That naturalist effectually disposes of the popular idea, not yet banished from scientific works, that the "free-flying" life of the cockchafer beetle is exceedingly ephemeral. We are sorry to learn that their mischief-working lives are much more extended than we imagined. Whether in our hot climate the periods both of grub and winged life, are not shortened is a question for solution. We shall all agree that their continued existence in any stage could well be dispensed with. And yet, who can say? in view of the mischief the man who replaces forest by coffee is accused of doing by disturbing "the harmony of nature." The cockchafer "cusses": the "notorious *Melolantha vulgaris*," 'May bugs" or "dors" (not from *dormancy* by any means, but from their humming), may be necessary to the harmony of nature, however, discordant their notes may seem to us. In that case Mr. McLachlan's final recommendation, that a small experimental garden should be established, in which the pests must be bred in order to be observed, will not seem so very preposterous. Mr. McLachlan is utterly unable to suggest any poison to which the beetles might be partial. Whiskey toddy is too expensive to be tried, but an experiment might be made with Paris purple, or red, or green, mixed with coarse jaggery?

Turning to Miss Omerod's "Manual of Injurious Insects," we find the cockchafer associated with the oak and described thus:—

The Cockchafer, known as the May Bug, is injurious both in the larval and perfect state. As a grub it feeds under ground on the roots of grass, vegetables, and young trees; as a beetle it feeds on the leaves of Oak, Elm, and other trees, sometimes entirely stripping the foliage. The eggs are white or pale yellow, and are laid (early in the summer) about six or eight inches below the surface of the ground, the female burrowing down to deposit them, and laying thirty or more, near together amongst the disturbed earth.

The grubs are thick and fleshy, white or yellowish in colour, with strong jaws, and three pairs of legs; and usually lie on one side, somewhat curved together. At the commencement of spring they come up to within a few inches of the surface of the ground, where they feed on roots of growing plants; and at the end of the third summer, when full fed, they again go down into the earth to a depth of two feet or more, and change to pupæ in oval cells.

During the following winter they develop into the perfect chafers, but do not come up through the ground until the next summer, that is, the fourth year since they were hatched, when they may be found as early as May hanging half-torpid or sluggish beneath the leaves during the day, and coming out on the wing during the evening, when they fly in search of their mates or feed on the foliage of the trees.

Then come

Prevention and Remedies.—When the May Bugs or Cockchafers appear in the large quantities sometimes recorded, as when eighty bushels are stated to have been collected on one farm ('Encyc. of Agriculture,' 2nd ed., p. 1,166), it is worth while to heat or shake them from the trees, preferring noon-time or early on a bright warm day, when the beetles are clinging beneath the leaves and are dull and sluggish.

They may be shaken down on to large cloths spread beneath the tree, or may be swept together and destroyed taking care in either case that the chafers are collected before they have time to recover from the fall and take wing; or, as pigs and poultry devour these beetles greedily, it would save trouble to drive them below the trees and shake the chafers down to them, Poultry would take some time about the work, but pigs would make a rapid and effectual clearance.

In field or garden cultivation, where many grubs are turned up by the spade or plough, some means should be taken for destroying them, Hand-picking by children is of use, but probably in the fields the pigs would be the better helpers. Their instinct and fondness for the grub makes them hearty and well-qualified searchers.

Wild birds, such as Rooks and Sea Gulls, should on no account be driven off. The Black-headed or Peewit Gull follows the plough in the same manner as the Rooks, and feeds on cockchafers both in the grub and beetle stages; the Common Gull will go for miles inland to follow the plough in search of insects and grubs; and the Nightjar, by "feeding almost entirely on cockchafers and moths" during the morning and evening hours, is also of great service.

In pasture lands, where the grass has been seriously injured by cockchafers grubs feeding on the roots, much service has been done by Rooks turning up the grubs and devouring them: in such cases the birds should be carefully protected from molestation; they pull up little—if anything—more than the infested plant (which would have died), and are in this case almost our only means of clearing off these large grubs, which otherwise excepting when changing their skins or torpid during severe cold, would continue feeding for three years.

In garden cultivation, where the ground is infested, a tame Rook is of much service. The bird will set to work as soon as it is introduced, and keep on steadily at the task, clearing the grubs from spots that could not be reached otherwise without injury to the plants. —(W. S.)

From the circumstance of the cockchafer grubs feeding amongst roots and giving no signs of their presence till the fading of the attacked plant draws attention to the injury going forwards, it is difficult to find any remedy, excepting by means of the insectivorous birds, which appear to have an instinctive knowledge of the position of the larva below the surface; but where examination of the roots of injured plants shows this grub to be present, it would be worth while to try the effect of good drenchings of some fluid, such as tobacco-water (properly diluted), gas-water, fluid drainings from pigsties, or anything else preferred that would not be injurious to the plant, but would be sufficiently offensive to the grub to drive it from the roots.—('Brit. Birds,' 'Illus. Brit. Birds,' &c.)

When in Australia we visited a vineyard where 200 turkeys had been turned out to abate a plague of grasshoppers. But the insects were on the surface of the ground. Turkeys here are too expensive and delicate for the purpose and we fear to propose even flocks of common fowls, because of the objections that if hawks or jackals did not attack them, they would be speedily disposed of by *Ramasami vulgaris*, who would probably plead the affinity of *kuli* with

koli. We had hoped at one time to try an experiment with the large Australian shrikes, known as "magpies," but this valuable insectiverous bird is carefully protected. How bird life is to be introduced and permanently retained on our plantations is the problem. Where are they to find food when grubs are not available. A few small birds came to feed on the seeds of the cinchonas, while gums and grevilleas encourage others, but progress is very slow. The forests which coffee plantations have replaced were singularly destitute of bird life, but prominent were flocks of minas. We know what has become of the jungle fowls and pigeons, but what has become of the minas, eminently insectivorous as those birds are? We fear the coolies have been allowed to shoot everything indiscriminately. Of another and allied beetle, the Green Rose Chafer, *Cetonia aurata*, Miss Omerod says:—

This chafer is injurious both in the larval and perfect state. In the first—that is, as a grub—it feeds on the roots of strawberries, grass, and other plants; as a beetle it frequents many kinds of flowers, including the rose, from which it takes one of its names; but is more especially injurious by its attack on strawberry-blossoms, and to the flowers of turnips left for seed, where it eats off the anthers frrm the stamens and thus renders the flowers abertive.

The eggs are laid in the ground, where the maggots hatch and feed for two or three years. When full-grown they are upwards of an inch and a half in length, thick and fleshy, of a whitish colour, with an ochreous head armed with strong jaws; the pairs of short feet are of a rusty ochreous colour, and the hinder portion of the grub or maggot is enlarged, curved towards the head, and of a lead-colour. These grubs are much like those of the cockchafer, but are distinguished by having a horny rusty spot on each side of the segment behind the head, and by the body being clothed with transverse rows of rusty-coloured hairs; whereas the grub of the cockchafer is almost hairless, and is without the rusty spots.

And then

Prevention and Remedies.—The beetles are so large and so sluggish in dull weather that there is then no difficulty in taking them by hand; during sunshine they may be taken with a bag-net, and destroyed in any way that may be most convenient.

Where the maggots are numerous, they should be got rid of by turning over the soil, or by spreading neglected heaps of rich earth, old cucumber-beds, and similar places which they frequent, and hand-picking all that are seen. Poultry will help very much in clearing the grubs, if driven in whilst the ground is being turned over.

Where the attack is on the roots of growing plants, it will be found serviceable to have few tame Rooks or Sea Gulls in the garden, as they can dig down with their bills amongst the roots which could not otherwise be meddled with, and clear large numbers of the grubs without harming the plants.

The Rose Chafer when about to deposit her eggs will sweep round on the wing until she sees a suitable spot, and—hardly pausing from her flight—will disappear at once down any crack that may be open in the ground or into a nook amongst boards, or otherwise; and the grubs may be found in the decayed wood-soil that accummulates within old hollow trees. It is therefore desirable to remove all wood-rubbish, and also heaps of decaying sawdust that may attract the beetle or shelter the grubs.

So that the great remedies are insectiverous wild birds or poultry, remedies which are, in Ceylon, very difficult to apply. Indeed there is but poor encouragements at present to try any experiments, but better days will come and we may be able yet to rejoice in the practical disappearance of bug and grub and fungus.

Here we close for the present but we may resume the subject.

THE STATISTICS OF BRITISH INDIA.

In the volume sent us by the Indian Government there is ample information respecting the various railway systems of India, which shews the progress made since the first section was constructed by Mr. Faviell in 1856, and also the progress being made. But, as the figures only come up to 1882, and much later information has been published in connection with the Parliamentary Committee which has sanctioned large and important extensions, mainly on the broad gauge, we need not quote figures. So, with reference to demarcated forest reserves, we need merely mention that between 1873-74 and 1882, the area had increased from 10,000 square miles to 49,000. Forestry in India is now attended to by a large and well-trained service, who adhere generally to the system and principles elaborated by Dr. Brandis, to whose merits cordial testimony is borne in the latest number of the *Indian Forester*. The cinchona statistics are brought up to 1883, when on the several Government plantations in Sikkim there were 2,294 acres in cultivation, with 4,711,163 trees permanently planted, stock and nursery plants bringing up the total to 5,045,391. As yet, the larger proportion by far consists of red barks, the acreage in *succirubra* being 1,870 with 3,713,200 plants in the field. There are 275 acres of *C. Calisaya* with 662,998 plants permanently out, the grand total being 877,218. Of *officinalis* there are only 9 acres with 25,000 plants, but 138 acres under hybrids have 304,378 plants permanently out, stock and nursery plants bringing up the total to 354,078. The tendency no doubt will be to root out the red barks and to give special attention to the best Calisayas (including Ledgers) and the richest hybrids. There is a small plantation in Burma which has not been a success. The plants are given at

C. succirubra	47,706
,, *Calisaya*	21,418
,, *officinalis*	11,193
Total...	80,317

The Kalhati plantation, Mysore, with 35,735 plants had been sold to a private party. The acreage of the Nilgiri plantations is given at 847, in which the plants permanently out were 967,705, against plants raised since 1879—3,484,616. Unlike British Sikkim, where officinalis proved an absolute failure, the great majority of the plants on the Nilgiris are of this species, thus:—

C. officinalis	714,675
,, *succirubra*	183,498
,, *pubescens* (hybrid) ...	55,624
,, *Ledgeriana*	2,452
Hybrids and others ...	9,613
C. Pitayensis	44
,, *Carthagena*	10
,, *Santa Fé*	5
Total...	967,795

The "plants raised" during 1883, included no succirubra, which is significant, but there were no fewer than 577,500 officinalis, which shows the faith placed in this species. It at once found a home in the deep rich soil of Dedabetta and has yielded large quantities of bark far richer in quinine than any of the same kind ever received from South America. There can be no question in our mind that the reason why *C. officinalis* failed so largely in Ceylon was due to the stiff soil, and especially the cold

clayey sub-soil, conditions in which tea flourishes. Of *C. pubescens* 132,000 were raised; hybrids and others 51,000, Ledgerianas 4,356, Calisayas 902, Carthagena 3 and Santa Fé 2. We may take it for granted, therefore, that the Nilgiri plantations will henceforward be specially devoted to the best varieties of officinalis, Ledgeriana, pubescens and other hybrids, to the exclusion of succirubra. Those who, in Ceylon, have large numbers of red bark trees, will not fail to note these circumstances. There are figures for out-turn of bark collected, which show that in British Sikkim the annual collection has risen from 261,659 lb. in 1878-79 to 396,980 lb. in 1883. On the Nilgiris the collections had varied from 114,847 lb. in the first-named year to 250,000 in 1881 and 1882 respectively, and 135,017 in 1883. Most of the Nilgiri bark has hitherto been sold in the open market, but it seems probable that either a local manufactory of febrifuge will be established as in Sikkim, or that the bark will be sent to London chemists to be manufactured on account of Government. The figures for expenditure, produce and receipts show, that, in a mere money-point-of-view, the experiment of introducing the cinchonas to India has paid the Government well. The figures for the cultivation in private plantations are very imperfect, no information being available for the Nilgiris, where the vast majority of the private plantations exist. The returns as they stand give :—

For Bengal ...	331	acres
,, Mysore...	23	,,
,, Coorg ...	1,086	,, (calculated at 800 plants to the acre)
Total	1,440	,,

The plants returned for Coorg are 868,725 in the field and 177,000 (only !) of seedlings. We have no doubt that, if the Nilgiri and Wynaad plantations were included, we should get for British India, in private hands at least, 5,000 acres under cinchona, with 1,000,000 plants in the field and an equal number in nurseries. But it seems a great pity that planters do not supply reliable statistics.

In regard to tea cultivation, which for many years back has been entirely in private hands, the case is better, although in some respects there are serious defects. Could we accept the figures as they stand, we should take the number of tea estates which existed in India in 1882 at 3,407. But it is clear that the figures opposite Kangra, 1,890 estates (!) are made up by including small patches of tea. For, against the 1,890 estates are shown only 5,386 acres under mature plants, and 2,257 under immature, the total area under tea being thus 7,643, or only an average of 4 acres for each estate. In all Assam only 1,017 estates are shown, so that we may safely substitute 90 for 1890 in the case of Kangra, thus reducing the total of estates in India to 1,607 ? Of the 1,017 estates shown in the nine districts of Assam, 156,707 acres were stated to be under mature plants and 22,144 under immature, total area under tea 178,857. In addition there were 604,511 taken up for planting but not yet planted, so that there is a vast reserve available for extensions. The total yield of tea in 1882 was 45,472,941 lb., which gave an average yield per acre for all Assam of 290 lb. But the averages varied thus :—

Cachar	...	... 281 lb.
Sylhet	...	... 276 ,,
Goalpura	...	... 297 ,,
Kamrup	...	... 180 ,,
Darrang	...	... 361 ,,
Nowgong	...	... 367 ,,
Sibsagar	...	... 322 ,,
Lakhimpur	...	... 247 ,,
Khasi and Jaintia Hills	...	80 ,,

The latter figures ought to be excluded for they refer to only one estate with 20 acres bearing. The average yield of Assam estates, however, remains at under 300 lb. per acre, a figure which promises to be doubled in the case of Ceylon. The average for the Bengal group of estates is higher, 309 lb. per acre. This is mainly due to Jalpaiguri, the Darjiling Terai, showing the exceptional figure of 399 lb. per acre, while the Darjiling estates are down for 302. The number of estates given for Bengal are 314 estates, with 36,096 acres under mature plants, 12,032 under immature, total area under tea 48,128 acres, and 46,107½ not yet planted. The yield of tea in 1882 was 11,172,404, or, as we have shown, 309 lb. per acre, a large increase on the previous year when only 261 lb. average per acre was shown. The figures varied thus :—

Darjiling	...	... 302 lb. per acre
Jalpaiguri	...	... 399 ,, ,,
Dacca	...	... 110 ,, ,,
Chittagong	...	... 323 ,, ,,
,, Hill Tracts	...	279 ,, ,,
Hazaribagh	...	... 110 ,, ,,
Lohardugga	...	... 170 ,, ,,
Mymensing	...	... 112 ,, ,,

Darjiling gave 8,080,293 lb. and Jalpaiguri (the Terrai and Dooars ?) 1,865,801, out of the total of 11,172,404. As Darjiling and Jalpaiguri are the chief competitors Ceylon high country and low will have to contend with, we quote the details for both :—Darjiling 165 estates ; under mature plants 26,716 acres ; immature 5,854 ; total under tea 32,570 ; land in reserve 12,282; yield of tea 8,080,293 lb. average per acre 302 lb. Jalpaiguri 60 estates ; under mature plants 4,670 acres ; immature 3,598 ; total under tea 8,268 ; yield of tea 1,865,801 lb. ; average per acre lb., 399 the highest in all India, the only figures exceeding 300 per acre being :—

In Assam	Darrang	...	361
	Nowgong	...	367
	Sibsagar	...	322
In Bengal	Darjeeling	...	302
	Jalpaiguri	...	399
Travancore		...	371

In the North-West Provinces of India, on the sides of the Himalayas and in from 30° to 34° north latitude, there are the three districts of Kumaun, Garhwal and Dehra Dun, with 86 estates ; 5,672½ acres under mature plants ; 2,266½ immature ; total area under tea 7,939 ; reserve 2,417 acres ; yield of tea 1,271,320 lb.; average per acre 224 1-7th. Tea is a cosmopolitan plant but the cold of these Himalayan stations in winter will always limit the yield of "flush." We shall not soon forget the cold of a frosty evening, on a tea estate in the Dun (the *down* place, as compared with the Himalayan masses on which Mussoorie and Landour are seen perched at 7,000 to 8,000 feet elevation, the Dun being 2,000).

The Punjab includes only one district, Kangra, famed for its delicate teas. There is one estate at Simla, but is not in bearing. We have already shown the outrageousness of the figures 1,890 for estates. We believe 100 is too large a figure for what are known as estates. The acreage under mature plants is given at 5,386 ; immature 2 257 ; total under tea 7,643 ; reserve 2,432 ; yield of tea 1,218,519 lb.; average per acre 226 lb. We now come to Madras, in which Presidency the cultivation of tea at a high elevation, on the Nilgiris, although only in 11° north, has not been the success which was anticipated. The exceptional case of Travancore, with 371 lb. to the acre, which raises the average to 225 lb., shows what may be expected, when the plant is cultivated on the hills of this native state and in the Wynaad. The figures for estates in the Madras Presidency are 96, eight of the plantations being devoted to seed. The

acreage under mature plants is given at 3,847¼; immature 1,699½; total under tea 5,516¾; reserve 4,705; yield of tea 865,661 lb.; average per acre 225. We have noticed that the average is raised by Travancore, where 89 acres under mature plant are represented as yielding 11,150 lb. of tea, or 371 to the acre lb. On the 77 estates situated on the Nilgiris, the averag was only 229 lb. per acre, with 73 lb. in Madura and 30 in Malabar. Ceylon has gone quite ahead of Southern India in this matter of tea-culture, but we cannot doubt that the planters of Wynaad, Travancore and Coorg will yet take up the enterprize in earnest, *Our* difficulty, ere long, will be want of sufficient labour, we fear.

In British Burma there are 4 estates, 1 in Akyab and 3 in Tougho, with 153¼ acres of mature plants and 6 inmature, the reserve being only 31¼. The yield of tea was 16,553½ lb.; an average per acre of 108 lb. The forests of Burmah could, no doubt, grow tea well, but at present there is no labour. The figures for all India, as supplied for 1882, are, probably, still fairly applicable. Correcting the absurd figures 1,890 opposite Kangra; we get about 1,600 tea estates* for all India, with an acreage of mature plants of 207,862; immature 40,375; total area under tea 248,237, of which an appreciable proportion must be devoted to seed-bearing. Let us say the odd 7,862 acres over the round 200,000? The quantity of land "taken for tea but not yet planted" is considerably more than twice the cultivate area, the figures being 660,203¾. The quantity of tea yielded was 60,017,398½, of which only 995,792 lb. was prepared as "green." The average for all India was 289 lb. per acre, but, if we take only the great tea districts of Assam and Bengal, we get fully 300 per acre, thus:—

Assam	...	... 290 lb.
Bengal	...	... 309 ,,
		2) 599
		299½

or in round numbers 300 lb. per acre. How far this rate is susceptible of correction by excluding seed-bearing areas or of improvement, we cannot say; but we should think, that, when railways enable fertilizing substances to be applied, the yield can be increased. It seems clear, however, that Ceylon (if railway construction is not stopped and the roads are not rendered impassable by being left unstamped and unblinded) has, and always will enjoy, superior advantages of climate and facilities of transport as well as of labour probably. There is the great fact already fairly established that the average yield of tea in Ceylon may be taken at twice 300 lb. per acre, the figures for the best tea districts in India.

In coffee Ceylon has always taken the lead of India, but in both countries the plant has now fallen into "the sere and yellow leaf." There are only 15 acres returned as under coffee in Bengal. For Madras we get 17,887 plantations in 1882, but, of course, small native patches have been included to make up this number. The acreage under mature plants is given at 56,391; immature 9,064½; taken up for planting but not yet planted (much of the reserve will, no doubt, be suitable for tea) 46,012½. The total acreage is 11,468. The average yield of coffee per acre of mature plant was given at 196 lb. in 1882 against 287 in the previous year, 294 in 1880 and 325 in 1879. The fall in four years from 325 lb. per acre to 196 lb. shows the effects of leaf-disease, which in Ceylon also has brought down the average yield from 600 lb. to 200 lb. per acre. The cost of cultivation (upkeep) per acre varies from R42 in Tinnevelly and 66 to 22 on the Nilgiris to 237 in Malabar. The yield of coffee went down from 18,548,646 lb. in 1881 to 11,042,873 in 1873. "Malabar" fell off more than one-half, from six millions to three. The Nilgiris, including the Ouchterlony Valley and South-East Wynaad, fell from 10 millions to 6. For Mysore we get for "plantations" the outrageous number of 23,338. The area under mature plants is given at 78,608 acres, immature 20,332; reserve 45,796; total area 144,736. Here there was an increased yield in 1882, 4,469,087 lb. against 4,069,313 in 1881. But the rate per acre is given at only 57 lb. Of course the rate one European estates must be much higher. The cost of upkeep per acre is given at R5 (!) to 150 per acre. Coorg shows 4,672 plantations "exclusive of the unauthorized cultivation on pasture-land." The acreage under mature plants is given at 40,800; immature 7,350; reserve 27,772; total area 75,922. The yield was 6,902,000 lb. in 1882 against 13,721,000 in 1881. The rate per acre is only 224 lb. against 340 in 1881. The cost of upkeep is given at R25 to 100 per acre.

The figures for British India are thus:—

Plantations	...	45,898	
Mature	...	175,807	acres.
Immature	...	36,753½	,,
Reserve	...	119,580½	,,
Total	...	332,141	,,
Yield 1882	...	22,416,000	lb.
Do. 1881	...	36,341,000	,,
Rate per acre, 1882		128	,,

But the figures for the two feudatory states of Cochin and Travancore have to be added. Here "plantations" really mean proper estates, of which 17 are returned for Cochin, with 1,757½ acres under mature plants; 573 immature; reserve 5,920½; total 8,251. The yield was 706,515 lb. in 1882 against only 465,155 in the previous year. The yield was at the rate of 402 lb. per acre; cost of upkeep R23 per acre. For Travancore 62 plantations are down (against 74 for 1881); with 6,737 acres mature plants; 1,088 immature; 5,069 reserve; total 12,894. The yield in 1882 was 1,339,078 lb. against 1,815,050 in 1851, and the yield per acre (strange contrast to Cochin) only 169 lb. against 259 in 1881. The totals for Cochin and Travancore:—79 plantations; 8,494½ acres mature plants; 1,661 immature; 10,989½ reserve; total 21,145. The yield in 1882 was 2,045,593 lb. against 2,280,205 in 1881, and the rate per acre 241 lb. against 268. The grand totals for coffee in India are 45,977 "plantations"; 184,301½ acres mature plants; 38,414½ immature; 130,570 reserve; and total 353,286. The yield in 1882 was only 24,462,453 lb. or 133 lb. per acre average, against 38,621,844 in 1881. The yield in 1879 was close on 43 millions of pounds.

The exports of coffee from the ports of Cochin and Travancore had risen from 2,200,000 in 1880 to 3,233,895 lb. in 1882; a curious result, due, probably to a remission of export duty?

Our readers will thus see that tea, which some score of years ago was in the depths of depression, has revived and is progressing in India, while coffee in India as well as in Ceylon has fallen on evil days. Such tides of depression and vicissitude are common to all human enterprize, prosperity and adversity coming and going, apparently in cycles nearly coincident with decades. Let us hope, that, while the course of tea continues to be prosperous, coffee may once more revive and hold its head up with the best and most profitable of tropical products. The provision of facilities of transit is the one great aid which Government can give to such a result.

* One, belonging to the Assam Company, is over 6,000 acres in extent.—ED.

TEA PLUCKING.

At a general meeting of the Maskeliya Planters' Association on the 15th August, the following paper was read by the Chairman (Mr. T. N. Christie):—

Gentlemen,—The few remarks that I have to make on the subject of tea plucking, particularly as regards the merits of fine plucking, are based on the experience of one whose name, were I at liberty to mention it, would go far towards carrying conviction to your minds. The question as to which is the best method of plucking is, I suppose, the most important we have to consider in the cultivation—even more important than the *pros* and *cons* of heavy pruning. Coarse plucking and fine plucking, in all their degrees, have advocates in Ceylon at the present moment, but the fine-pluckers are in the large majority, although many of those who form that majority have inward qualms as to whether they are doing right or not. The coarse-plucker says: "You are plucking your bushes to death, your estate will be worked out in no time, and your yield is much less than mine." The fine-plucker says: "My yield is good enough, and my prices are 30 per cent better than yours, and as it costs almost as much to land a pound of tenpenny tea in London as it does to land a pound of fourteenpenny tea, my profits per pound are more than twice yours." I was myself told by many Indian planters that the high position which our teas attained last year (and from which I regret they have this year slightly receded) was due to our short-sighted, short-lived policy of fine-plucking. Anyone, they told me, could make high-priced teas by sacrificing the quantity of their yield and the permanency of their plants. I did not, however, consider what plucking I saw in India as being very coarse, and I fancy the Indian planter has of late been plucking finer than he used to do half-a-dozen years ago. At first sight, fine plucking does strike one as being more likely to exhaust our estates than coarse plucking, but when we look more closely into the facts the likelihood is much less apparent. As regards exhaustion of the *soil*, I think it is evident that say, 300 lb. of tea will take just as much, or just as little, from the soil whether the leaves equivalent to that quantity are 10 days or 15 days old. As regards exhaustion of the *plant*, perhaps more might be said in favor of coarse-plucking, but even in this aspect it may be doubted whether the physique of the plant appreciably benefits by leaving on the immature leaf for few days longer. The leaves from which we manufacture are all soft growing leaves, leaves that have not reached the stage of performing the functions of foliage, and their removal a few days sooner or later cannot make much difference to the plant one way or another. You all understand, gentlemen, that the same leaves are plucked under the two systems which we are considering, only in the one case they are plucked a few days earlier than in the other. What little difference the earlier removal of the flush may cause can easily be made up if the fine-plucker allows his bushes to "run" for an extra week or two before and after his pruning. We should aim at getting foliage below the pruning level, and this can be obtained by topping-back our plants at an early age. The information which I have received shows that the loss in quantity by fine-plucking is not nearly so great as the coarse-plucker, particularly the Indian coarse-plucker, thinks. On an estate where the plucking, although never very coarse, was much coarser than it has been during the past 18 months, one patch has been plucked fine for two-and-half crops, one field for two crops (and this field has kept up the quantity of its yield from the time it was plucked fine), and the whole estate plucked fine for one-and-half crop. None of the bushes are in any way harmed, and, now that they are being pruned, they look well for the coming crop, having plenty of fine clean "pipes" of young wood to grow new flushes on. From the primary shoots that grew on the wood left after pruning, only the bud and one leaf were taken, and the yield in the beginning fell behind the previous year's yield at about 4,000 lb. tea, but since then the yields have run alike, and the yield for the year will not be more than 4,000 lb. under the previous years yield, which was the largest the estate ever gave. Besides, the fine tea made from the first plucking left far more profit than would have accrued from the larger quantity which would have been obtained, had another but harder leaf been taken. The crops from the same average of tea, in full bearing all the time, have been :—

1884 ...	350	lb.	tea per acre—	plucked fine throughout.
1883 ...	392½	,,	,,	most of the estate plucked coarse for half the year.
1882 ...	311	,,	,,	plucked coarse.
1881 ...	360	,,	,,	

These figures, gentlemen, I believe to be amongst the most reliable we have in Ceylon, and the experience so far is that, practically, diminished yield has *not* followed fine-plucking. A larger force of coolies has been required, and the cost of plucking has been much more, although but a trifle compared to the increased value obtained in the market. Another estate, which with the old style of plucking was estimated to give 600 lb. per acre, yielded with fine-plucking 560 lb. per acre. I trust that any gentlemen present who have experience, however limited, in plucking will give us the benefit of their opinions.

REPORT ON THE GOVERNMENT CINCHONA ENTERPRIZE IN JAVA FOR THE 2nd QUARTER 1884.

(*Translated for the "Ceylon Observer."*)

April and May were characterized by incessant rain. The long-continued wet was not conducive to the regular progress of things. Although a large number of plants could be put out, the harvesting of bark was considerably delayed. Then when at the beginning of June the dry monsoon suddenly set in, the labor began to fail as speedily, needed as it was for the picking of coffee and for the very large paddy harvest. During the long-continued rain the available labor force was employed chiefly in thoroughly working the soil, with the view rather to promote the formation of bark than to gather the product, which is obtained in unfavorable weather at so much greator expense. Although therefore the harvest of bark in the first half-year of 1884 will be smaller than that in the corresponding period of 1883, the prospects of the produce, so far as relates to the quality, are certainly better than in the previous year and will not be behind those of 1883. The harvesting was confined almost entirely to the thinning out and pruning of those trees which had become thickly entangled with one another. Very little has as yet been done in the removal of inferior varieties for the substitution of Ledgerianas and succirubras. Of the bark gathered during 1883, 78,524 Amst. lb. were dispatched last June to Batavia. 493 lb. were reserved for the local military medical service. In the packing-houses and on the estates there are still about 40,000 lb. of bark, a great part of which is waiting for the needed packing materials. The so much higher prices which pharmaceutical barks unbroken, and especially long quills, at present fetch in the European market make it desirable to dispense with the ordinary packing in jute bales and to give the preference to export in cases. The necessary perparations are being taken for carrying this out, and meanwhile the bark quills remain heaped up in the packing-houses. The results of a thorough and deep working of the soil, which is now being generally practised on all the estates, are making themselves more and more

felt, and a vigorous growth can be noticed everywhere, especially since the setting in of the dry weather. At Tjinjirocan a new nursery-house for artificial propagation was completed, and a commencement was made with the building of a similiar structure. With a larger labor supply than has hitherto been available the bedding of grafts can now be proceeded with. For grafts the twigs of picked Ledgerianas which on analysis yield more than 10 per cent of quinine are now exclusively employed. With the supply at present in the nurseries and grafts which will be obtained in the course of this year the plantation, at Tirtasari will be considerably extended in the next west monsoon. A commencement is now being made with the clearing of the forestland needed for this. The raising of Ledgeriana seedlings was carried on vigorously on nearly all the estates, in order that the plantations of inferior varieties which have yet to be rooted up may be as soon as possible replanted. During the past quarter only once—on 4th April—was a sale of cinchona seed held. On account of want of competition the sale realized only a sum of *f*650. Not a single bid exceeded the minimum fixed by Government. Of the southern estates only the succirubra plantations at Rioenggoenoeng had to endure a severe attack of *Helopeltis Antonii*. The Ledgeriana plantations have been preserved from the pest by a thorough pursuit of the insect. The insect showed itself again at Lembang, which estate had been spared for a whole year. By the catching of the insect and the removal of the infected leaves the damage has been reduced to a minimum. Apparently as a consequence of the long-continued wet, a fungus, entirely distinct from the well-known *djamoer oepas* on coffee, began to show itself here and there, especially in the dense plantations at Tirtasari and Tjibenreum. By the cutting off of the affected tops and branches the disease was combated as far as possible, and the damage done is of little consequence.

Van Romunde,
Director, Govt. Cinchona Enterprize.

Bandoeng, 4th July 1884.

CORRESPONDENCE ON THE COFFEE GRUB.

(From the *Ceylon Government Gazette.*)

His Excellency the Governor has been pleased to direct that the following copy of a letter from Mr. Thiselton Dyer, and of its enclosures, be published for general information.

Mr. Thiselton Dyer to the Colonial Office.

Royal Gardens, Kew, July 1st, 1884.

Sir,—I am desired by Sir Joseph Hooker to inform you that he has been officially requested by the Director of the Botanic Gardens, Peradeniya, Ceylon, (a copy of whose letter is enclosed,) to obtain a report upon a variety of documents and specimens forwarded to him, which illustrate the ravages of "grub" in the coffee plantations in the Colony.

Mr. Christie states that in the Maskeliya district "the damage first began to attract attention in 1877, and since then the grub has spread until some 4,000 acres are badly affected, and but few estates, except those very recently opened, have altogether escaped. He thinks the loss, exclusive of the depreciation in capital value of the estates in this one district from this cause, is quite £15,000 per annum." He adds: "As a rule the trees are reduced to mere living skeletons, giving no crop, and are particularly liable to attacks of 'leaf disease.'"

The subject was referred to Mr. McLachlan, F.R.S., who has often assisted the Government in inquiries of this kind. After some delay, owing to various causes, he has furnished a report, of which I enclose a copy, and which appears to supply all the information upon the subject which is available in this country.

Sir William Gregory, who has recently returned from Ceylon, has kindly furnished me with a letter, (of which a copy is enclosed,) which suggests a very probable explanation of the origin of the scourge. Of its severity there can be no doubt. Mr. Christie states that "the brown chafers fly in the dry months for about a quarter of an hour, just as it gets dusk, every evening, and their numbers are almost incredible. Several millions have been caught in one season on a single badly-affected estate."

Dr. King, the Superintendent of the Calcutta Botanic Garden, who is now in this country, has given us an instructive account of a similar but more limited visitation at Darjiling, where the grub of an unknown beetle has completely devastated the Botanic Garden. Here there seems to be no doubt that the insect found its starting point in the vast accumulation of refuse formed by the Municipality on an adjoining piece of ground. It appears from Dr. King's observations that the grub, which is probably quite similar in its habits to those afflicting Ceylon, comes during the hot weather to within an inch of the surface to feed on the roots of annual herbaceous plants. It can then to a large extent be destroyed by forking out. In the cold weather, it descends and feeds on the deeper-seated roots of shrubs (such as coffee), and it is at this time that it inflicts the most serious mischief on the planter, while it is practically inaccessible.

Under the circumstances, Sir Joseph Hooker, in accordance with the terms of Lord Kimberley's letter of February 23rd 1882, fixes the fee payable to Mr. McLachlan at ten guineas, which I am to request the Crown Agents may be moved to pay to that gentleman.—I am, &c.,

W. T. Thiselton Dyer.

The Hon. R. H. Meade, Colonial Office.

Enclosure No. 1.

The Director of the Royal Botanic Gardens, Ceylon, to the Director of the Royal Gardens, Kew.

No. 45. Royal Botanic Gardens,
Peradeniya, Ceylon, 3rd July 1883.

Sir,—I have the honor to send herewith certain papers and two boxes of specimens bearing upon the subject of "grub" in coffee, and I have to request that you will forward them to Mr. McLachlan, F.R.S., (or in the event of his declining the work, to some other entomologist accustomed to deal with agricultural questions) for report.

2. The entomologist is requested to give an opinion as to the best measures to adopt for checking the ravages of this pest which, in some districts of Ceylon, are of a very serious character. His fee will be paid by this Government.—I am, &c., Henry Trimen, Director.

Enclosure No. 2.

Mr. R. McLachlan, F.R.S., F.L.S., to Sir J. D. Hooker, K.C.S.I., F.R.S., &c., Director of the Royal Gardens, Kew.

West View, Clarendon Road,
Lewisham, London, S.E., June 1884.

Sir,—In the autumn last year I received from W. T. Thiselton Dyer, Esq., C.M.G., F.R.S., &c., Assistant Director, Royal Gardens, Kew, sundry documents and specimens connected with the ravages of "grub" on coffee &c., plantations in the Island of Ceylon, accompanied by a request that I would report thereon. I was also favoured with a private letter from Dr. Trimen, F.L.S., of the Royal Gardens, Peradeniya, in connection therewith. I deeply regret the delay that has occurred in submitting this report, occasioned partly by the magnitude of the subject as illustrated by the box of specimens sent, and partly also from periods of indifferent health.

In consequence of the large mass of specimens it was necessary that they should undergo examination by some entomologist who has made these families of beetles an object of special study from a systematic point of view. This has been done, but in many cases with the result that little more than the generic name can be given. A considerable number of the species have no doubt never been described, and others belong to genera in which the specific characters are of a very obscure nature. In all, fully 40 species of beetles are in the box.

Referring specially to those species indicated by numbers in Mr. Braine's letter No. 1, I find the following:—

1. *Leucopholis pinguis*, Bunn. (The "big patana cockchafer"), also a second species of the same genus indicated "from Ralapara." [?—Ed. C. O.]
2. *Euchlora* sp.
3. *Anomala* sp.
4. *Mimela xanthorrhina*, Hope.
5. *Ancylonycha Reynaude*. Blanchard (perhaps the "yellow-bellied chafer.")

6. *Rhinophilia* sp.
7. *Sericа* sp.
8. *Apogonia* (or new genus?)
9. *Adoretus* sp.
10. *Ancylonycha* sp.
11. I cannot find.
12. Probably same as No. 10.
13. *Ancylonycha* sp. (the "Maskeliya chafer.")
14. *Ancylonycha* sp.
15. *Adoretus* sp.
16. *Apogonia* sp.
17. New genus allied to *Apogonia*.
18. *Anomala* sp.
19. *Adoretus* sp.
20. *Adoretus* sp.

In addition to the foregoing there are many species of *Celoniadæ*, a few stag-beetles, a Buprestis (*Campsosternus Templetonii*, Westwood), one species of *Passalidæ*, sundry *Histeridæ*, *Tenebrionidæ*, *Scarabæidæ*, &c. The *Celoniadæ* are probably indicated as "carpenter beetles" in Mr. Braine's letter, but the term more correctly belongs to *Longicornæ*, which are not represented.

Dealing with the subject purely as "grub," it appears to me that with regard to the insects forwarded the interest is specially centred in the *numbered* species, for all or nearly all of them are close allies of the notorious *Melolontha vulgaris* (the common European cockchafer). The larvæ of stag-beetles feed on the wood of trees, and from the size of those sent it is probable these were bred in some large tree near the coffee plantations, rather than in the coffee plants themselves. The Buprestis may have lived as a larva in the stem of the coffee. The larvæ of others feed in dung or in decaying vegetable matter. The *Celoniadæ* may or may not damage the coffee roots as larvæ, and it may be assumed as certain that the beetles damage the flowers by feeding on them and preventing fructification by destroying the stamens and pistils; therefore it is essential that perfect beetles should be collected and destroyed when the plants are in flower.

Returning to the *chafers*, which no doubt are destructive both as larvæ and perfect insects. It may be taken for granted that any larva that eats the young roots of a plant must damage that plant, and if the larvæ are in sufficient numbers, and the attacks be persistent, the plant must succumb sooner or later.

And this brings me to the points I., II., III., and IV. in Mr. Christie's report

In point I., a distinct statement, that the ravages of the "grub" do cause the "emaciation" of the coffee trees, is asked for. Here I would call special attention to the paragraph almost immediately preceding marked*. The insects accused of doing the mischief are most nearly related to the European cockchafer. The larvæ (or "grubs") of these insects feed on the roots of plants, and the very circumstantial evidence afforded by the reports of Messrs. Braine and Christie, and Mr. Haldane's pamphlet ("All about Grub") can, in my opinion, leave no doubt that the Ceylon chafers conform to the habits of their European allies. [In connection with this a statement of some importance will be found (*vide post*) in the consideration on points III. and IV.] Then there is a "suggestion" put forth by some planters (alluded to also in Mr. Haldane's pamphlet, p. 11) that the grubs do not attack healthy plants, but only those that are sickening from some other cause or causes. In the case of beetles, the larvæ of which bore into or feed under the wood or bark of trees and shrubs, this "suggestion" would probably prove abundantly justifiable. But we have to deal here with quite another method of attacking the plants. The tribe of cockchafers are root-feeders in the larvæ state, and according to all previous evidence they prefer plants in which the roots are succulent and in a presumably general healthy condition. Therefore, I would rather assume that plants attacked by "bug" or fungus may have already had their constitution injured by the unsuspected presence of "grub" at the roots. Different groups of insects have distinctly different proclivities in their tastes, and the conditions that might be eminently favourable for one might be equally unfavourable for another.

Point II. concerns the probable duration of the active life of a chafer, and it is stated that some planters maintain that a female chafer flies for one evening only. This latter opinion may be dismissed as absurd, and it is probably based on some idea connected with the life of a May-fly (*not* "*May-bug*") and incorrect even for that. I think it probable that a chafer may exist as a free-flying perfect insect for weeks. [I used the term free-flying because, in the European cockchafer, there is evidence that the transformation from the pupa to the perfect insect ordinarily takes place long before the latter emerges into open air.] Formerly it used to be considered that when insects once paired, the male died immediately, and the female followed so soon as her eggs had been deposited. This has been disproved in so far that both males and females may pair several times, and with different partners, and that both sexes sometimes live long after the procreative business of their lives has finished. A far more serious consideration is the duration of the insects as "grub." This the parties interested in Ceylon must decide for themselves by observation and experiment. With regard to the smaller chafers (*Ancylonycha*, &c.) I should think that one year would suffice for the complete life-cycle from the deposition of the egg to the death of the beetle produced therefrom. We here, in England, would be apt to conclude that a much longer period would be necessary in the case of the "big patana cockchafer" (*Leucopholis*); but on this point Mr. Haldane, (who has carefully read up the literature at his command, and judiciously reasoned thereon,) points out that although more than three years may be necessary for one cockchafer to go through all its transformations, the same rule may not apply in Ceylon where there is practically no dormant season, and that there the transformation may perhaps be effected much more rapidly.

Points III. and IV. may be taken together. They are the most important and, at the same time, the most difficult to consider. We are not dealing here with a special insect attacking a special plant. The *Phylloxera* of the vine may be taken as an example of the latter class, and one that *should* be the more easy of attack, because all its life is practically passed in *one* condition underground. We have to deal here with enemies the larvæ of which will probably feed on the roots of any plant, and which in the perfect state can shift their quarters at pleasure.

Here I would first of all call attention to one special point. I surmise that in the coffee plantations no *undergrowth* of grass or other herbaceous plants is allowed to exist. A distinct understanding on this point appears to me to be of very great importance. The grubs of the European cockchafer and its allies do not *as a rule* feed on the roots of trees and shrubs, but on those of grass and herbaceous plants. Supposing a certain amount of analogy to exist in the habits of the Ceylon species (and analogy in habit should always be suspected in closely allied insects), the keeping of the plantations perfectly free from weeds and undergrowth should be of paramount importance. Judging from analogy, the grubs should prefer the roots of the weeds to those of the coffee, and the females should be attracted in much larger numbers by the presence of weeds than by the coffee only; but from the roots of the former they would make their way to those of the latter. But taking it for granted that the plantations are kept perfectly clean, other matters have to be considered. In analogous cases it has been suggested that the earth from some distance round the roots of the plants should be battered down by a spade, and hardened, so as to render it difficult for the female insect to deposit her eggs. This suggestion is not without its importance, but the planters themselves must consider its practicability in connection with the welfare of the plants at the time the eggs are laid. Hardening the surface might prevent the deposition of eggs; it might also cause the rain to run off instead of penetrating. With regard to chemical remedies, (I am here considering only "grub,") I have little to suggest. According to the reports submitted to me, several of the most approved remedies of this nature have been tried with more or less success. If any one in particular gives evidence of more than usual success, I would advise that its use should be continued. Saturating the earth round the plants with dilute kerosine-oil should be tried. In France, the use of bisulphide of carbon by "injection" into the soil round the vines by instruments made specially for the

purpose, appears to be the most approved method of counteracting the ravages of *Phylloxera* by chemical agents. But, as before stated, the conditions of *Phylloxera* and "grub" are by no means parallel. In the case of the former, when the insects are once thoroughly destroyed, the necessity for continuing the application of the remedy is almost at an end. In the case of "grub" the application must be continuous month after month, or year after year and in the long run the soil itself might be rendered poisonous to the plants. I am utterly unable to suggest any poison "*to which beetles might be partial.*"

Above all things, encourage insectivorous birds to the fullest possible extent. In Europe, starlings, crows, and gulls hold the first place as destroyers of chafers' grubs. A flock of crows probably destroy more grubs in an hour than would be possible by any "artificial" means in a week.

I am asked to state that systematic catching of the perfect insect or larva would be beneficial. The benefit of such a proceeding must be self-evident. Anything that lessens the numbers of a destructive insect must of necessity be beneficial, and where the labour is cheap hand-picking should be resorted to extensively.

I may be permitted to conclude with a suggestion that appears to me of great importance. It appears to be admitted by all but a certain class of planters that "grub" is causing great damage to the coffee plantations, and the evidence before me appears to amply confirm this. Therefore it is highly desirable that the Planters' Association or the Ceylon Government should establish an experimental plantation of a few acres in which the natural history of the various kinds of grub, and the effect of various supposed or real remedies, could be carefully watched.—I beg to remain, &c.,

R. McLachlan, F.R.S., F.L.S.

Enclosure No. 3.

Sir W. H. Gregory to Mr. Thiselton Dyer.

3, St. George's Place, Hyde Park Corner, June 18th, 1884.

My dear Sir,—You are welcome to my opinion as to the cause of the prevalence of the cockchafer grub which is ravaging Ceylon, but which might be greatly reduced. It is pitiable to see the widespread ruin it has caused. In no case does the coffee tree recover in less than two or three years; in many cases, unless the plant is very healthy, it never recovers.

The chief ravages are on estates close to "*patanas*," that is rolling upland prairies. Formerly these were grazed by the cattle of natives and of settlers, and in order to obtain sweet grass these patanas were burnt annually in the dry weather at the time the cockchafer lays her eggs; of course the eggs were burnt and the spread of the insect was kept down. Now, the planters will not burn the 'patanas' themselves or allow the natives to burn them. They cut the long coarse grass and put it as litter under their cattle, which are kept in sheds. Some planters say in excuse that estates are ravaged which are at a distance from patanas, but the fact is that the cockchafer has so increased that it has spread far and wide.—I remain, &c.,

W. H. Gregory.

INTERNATIONAL FORESTRY EXHIBITION AT EDINBURGH.

In a building over two hundred yards long, with three transepts, each one hundred yards in length, and in the surrounding grounds of eight acres, the Scottish Arboricultural Society and its other promoters have collected an exhibition of unrivalled interest to all classes of the community. Timbers, fibres, gums, indiarubber and paper which may be made from wood, not to speak of charcoal for gunpowder and innumerable small wooden articles, are in use by us all, and we should all take an intelligent interest in their supply and manufacture. England, though not rich in forests at home, owns in her colonies far more forest-land than any state in the world, and is yet the only country in Europe, of even second-rate importance, that has no school for the teaching of forestry. A school for native forest officers exists at Dehra Dun, in the North-West Provinces of India; but their English superiors, trained till recently at Nancy, are now educated at the Engineering College at Cooper's Hill. It is to be hoped that part of the highly instructive collections now at Edinburgh may be permanently kept together so as to form a museum and the *pièce de résistance* of a school of forestry for Britain.

Though Japan has characteristically bespoken a whole transept, and a magnificent Indian collection arranged by Col. Michael already overflows from the half of another, the Home Government is by no means inefficiently represented. On entering the building, the eye is caught by a stand of lances of ash and bamboo, with pennons flying, sent by the Secretary for War, who also exhibits specimens, polished and unpolished, of the various woods used in the royal arsenals, including Italian walnut in the stalks of Sniders and Martini-Henrys, and willow, alder, and "dogwood," for gunpowder charcoal. It is to be regretted that these woods are not scientifically named, as the ordinary visitor will not know what to make of "pedouk" or "sabiga," may be misled by the name "cedar" attached to woods from Mexico and Cuba, and may not recognize British Guiana in the description, "America," given as the locality for greenheart.

Close at hand the Commissioners of Woods and Forests make a fine display from Dean, Windsor, and the New Forests of timber of various ages, grown on different soils, and the tools used in felling, bark-stripping, &c. Among this collection are sections of Spanish chesnut, 170 years old, from Bagshot Park, about 3½ ft in diameter at 5 ft. from the ground; Cedar of Lebanon, from the same place, 120 years old, 76 ft. high, represented by a plank 56 ft. by 3 ft.; oak from Windsor, 60 years old, yielding a 30 ft. plank over a foot wide; and larch grown nearly 200 ft. above the Severn, in Dean Forest, and in seventy years becoming nearly 3 ft. across, at five feet from the ground.

Whilst this shows what may be grown in England, the Scotch foresters and members of the Aboricultural Society are not behindhand in exhibiting what can be done further north. Their larch, though slower in growth, is remarkable for its large proportion of heart to sap wood, a characteristic still more true of the Scotch fir as grown on her Majesty's estate at Balmoral. From the Munches estate, Dalbeattie, is sent a young Douglas fir, three years old, 11 ft. high, and 3 in. through; whilst other specimens of the same species from Tullibardine are more than a foot through when sixteen years old, having made rings more than half an inch across for several years. Some posts and railway sleepers, perfectly sound after seven years' use, sent from Skibo Castle, Sutherlandshire, testify to the durability of this species and of the silver fir. Equally practical are the numerous wood sections in the western transepts, showing the effects of bad and good pruning; whilst one of the most beautiful objects in the exhibition is a library table inlaid with 10,000 pieces, including 117 specimens of woods grown on the Morton Hall estate, Liberton, and made by the forester, Mr. D. F. Mackenzie.

Science, as well as practice, is represented by the exhibits of the Arboricultural Society, including meteorological instruments and a variety of simple forms of dendrometers, of which the best seem to be those of Messrs. James Kay and D. F. Mackenzie. Near at hand, Messrs. J. Davis & Co. exhibit various forms of their Royal Polytechnic barometers, including Admiral Fitzroy's weather forecasts and a separate indicator for winter and summer, making altogether a very ornamental and complete weather-glass.

In the north-west transept, Messrs. Vilmorin-Andrieux exhibit a magnificent series of cones, fruits and seeds of forest trees, especially oaks, pines, firs, palms and eucalypti. One cone of Pinus Lambertiana is 15 in. long and 4 in. through at the base. They also show from Antibes specimens of Eucalyptus globulus and Acacia dealbata, each two years old, and respectively 5 in. and 4 in. in diameter. An accurately-named collection from Messrs. James Veitch and others from the Lawson Seed Company and Messrs. Little and Ballantyne, render this department of the exhibition very complete and well worthy of the attention of all landowners and their estate managers.

In various parts of the building there are fine series of microscopic sections of woods; but except for some live pine beetles from Balmoral, and some cases of American insects from Dr. C. V. Riley of Washington, not yet displayed, the exhibition is weak in the depar ment of forest entomology.

Cyprus sends a small but interesting series of specimens, which are carefully described in the catalogue (which, by the way, even in the incompleteness of a first edition, is a perfect mine of information); but of more importance to those about to emigrate, or otherwise interested in our colonies, is the series from Cape Colony. Among many species remarkable for beauty, hardness and durability, the yellow wood (Podocarpus), the stinkwood (Oreodaphne bullata), the sneeze-wood (Pteroxylon utile) and the black ironwood (Olea laurifolia) may be specially mentioned. A cheaper supply of labour seems to be all that is required to render the production of timber, for furniture and perhaps engraving, at the Cape, an industry of first-rate importance. The sneeze-wood, locally used for fencing, is remarkably durable, and the black ironwood seems suitable for engraving.

The Mauritius section is mainly remarkable for the extensive series of fibres, produced from a great variety of plants, which it includes. Some of these seem worthy of more attention than they have yet received. Denmark sets a good example to Europe in the care with which the statistical information contributed to the catalogue by its government has been compiled, and in the excellence of the maps of its forests. The chief trees grown in this country are beech, oak, and red spruce (Abies excelsa) and it exports hard wood; and, though importing more than 90 per cent of the fir-wood used, shares with Norway and Sweden in the manufacture of paper pulp from pine-wood. This last mentioned industry, one of supreme importance, is represented in the exhibition in a manner that has never been seen before in this country.

British Guiana and St. Vincent make a very creditable show in the north-centre transept, the large logs of greenheart (Nectandra rodiæi), mora (Mora excelsa) and other valuable timbers, illustrating the importance of forest conservation in the colony, as do also the photographs showing the reckless methods of clearing now in vogue; but the gem of the exhibition is on the other side of Messrs. Stuart's salmon ladder and big central fountain—the Indian collection. The description of this, with an interesting historical preface by Sir George Birdwood, occupies seventy pages in the catalogue, and includes not only a list of all the timber trees and forest products of India, with their scientific names, but also a detailed account of the more important of the *modus operandi* of the Forest Survey Department, of the mode of preparing turpentine and resin from the Khasi-pine and of the use of sal bark, a newly-discovered tanning material, with a bibliography of Indian forest literature. The large series of forest maps, on scales varying from thirty-two miles to the inch to eight inches to the mile, prepared and arranged by Major Bailey, add much to the scientific value of the collection, which as a whole does credit to the hard work bestowed upon it by Col. Michael.

Burmah is represented by a magnificent beam of teak, and by specimens showing its applicability to parquetry, wooden pavements and other uses in which small pieces can be economically employed; and the neighbouring territory of the Maharajah of Johore sends a very complete little collection of woods, fibres, rattans, camphor, guttapercha, indiarubber and catechu. This friendly state, affording plenty of large sport, such as elephants and tigers, seem also to offer considerable inducements to traders.

New Brunswick, a colony whose attractions seem to be mainly agricultural and mining, sends a small series of native woods, including maples and others of great beauty. There are forests of hemlock spruce in this colony, which certainly demand conservation, and it is much to be hoped that one of the results of the conferences which it is proposed to hold at Edinburgh may be to arouse foreign and colonial governments to the wide-spread necessity for such precautions against wholesale disafforesting.

Among miscellaneous exhibits at the east end of the building, and in a north annexe, are series illustrating the woods used in coach building, shown by Messrs. Offord; coconut products, from Messrs. Treloar; indiarubber in the crude, cleaned, vulcanized and manufactured state, shown by the North British Rubber Company; turpentine and other pine products from North Carolina, exhibited by Messrs. Fleming, of Edinburgh; American white oak, as used for railway waggons from Messrs. Kennedy of Glasgow; bread platters, butter prints, &c., in the white wood of the sycamore, which in Scotland is commonly called "plane," made by Messrs. J. and W. Gow of Glasgow and Edinburgh; and several sets of furniture, and of carpenters' and foresters' tools. An important object is the elastic waterproof composition and the liquid varnish shown by Mr. Wells of Leith. These are preparations, the one in paste and the other a liquid spirit, prepared mainly from marine glue and the fusel oil obtained as a waste product in the manufacture of whiskey. The paste is recommended for filling wounds in trees caused by accident or bad pruning, and the liquid, which is a quick drier and very penetrating, either as a substitute for creosote—as which it is already much used in ship building—or, when applied as a waterproofing to stout paper, to protect trees from rabbits. For a similar purpose Mr. Ahlbotta, of Leith, exhibits a Tree Protective Composition, largely composed of Archangel tar, paraffin and oil, with some lime in it, which is applied to the bark itself. It has been tested for some years, and is stated to be not not only not injurious, but actually beneficial to the tree. A case was also exhibited containing Mr. W. Smith's insecticide, sent by the manufacturer, Edinburgh.

In the exhibition grounds the centre of attraction is the Queen's châlet from Balmoral, built of Scotch fir, and ornamented with cones and moss. It contains some very neat and ornamental furniture, made on the estate from the same wood, and is flanked by two large planks, as also by the butt of a Scotch fir from Ballochbuie forest, 235 years old, containing 483 cubic ft. and giving over 23 ft. of girth at the base, though grown at an altitude of 1,500 ft. and by another tree, which has lain for forty years on its side, and is overgrown with heather and cranberries, and yet retains its heart-wood perfectly sound. The proportion of heart is very large and shows how good a return can be got from this species, even in the far north, and one of the poorest of soils, a ferruginous gravelly sand. Round the châlet the grounds are tastefully planted by the Lawson Seed Company, Messrs. Little and Ballantyne (who show a fine series of hollies and seedlings of forest-trees), and Messrs. James Veitch, who only exhibit single specimens, but

those very fine ones of Sciadopitys verticillata, Athrotaxis selaginoides, Cryptomerias, Retinosporas and maples.

Among a quantity of interesting machinery in motion, including a variety of sawing and planing benches, we were particularly struck by the tea-manufacturing machinery shown by Messrs. Greig of Edinburgh. This consists of the Globulous Pipe Hot-air Geoerator or tea-drying stove, one of great power and simplicity; a rapid drying or withering machine that can be used also for winnowing; the link and lever tea-rolling machine; a sifting machine, giving four graduated sieves a steady circular motion, and so saving much waste; and a green-leaf cutting and equalizing machine, consisting of a roller armed with cross-cutting knives. This series of instruments seem powerful, simple and inexpensive, and should enable the tea-planter to prepare and send to market tea of uniform quality, with a minimum of waste.

Enough has been said to prove the statement made at the outset that the exhibition at Edinburgh contains much matter of interest to everybody, and it is to be hoped that the public will insure its financial success and that the science and practice of forestry may benefit by it and the conferences which it is proposed to hold in connection with it.—*Field*.

THE FORESTRY EXHIBITION.

Edinburgh, 10th July.—The International Forestry Exhibition had its first big day on Tuesday, when the popular shilling became the charge for admission. To some extent the Executive have been unlucky, for on Saturday, for example, the first great popular excursion day of the season, the price remained at half a crown. It was a wet day, and thousands of visitors would have gone had it been a shilling, for a covered show is always popular. On Tuesday a great illumination fête was advertised for the evening, and a large crowd went. But just a little before eight, when many more would have been going, down came an awful rain, and it soon got dark inside, and the rain made outside illumination impossible so that the fête had to be postponed. They were not much more lucky on the next evening, so that what with opening before the thing was in order, and with mishaps of weather and so on, the managers have been rather unfortunate; however, we hope for better things.

In such an Exhibition two points have to be sedulously cultivated, the "popular" and the "practical." It has to be sufficiently attractive to bring the thousands of people who want to be amused, and whose money pays the expenses, and at the same to be valuable to the expert, who comes in dozens only, not in thousands, and whose money never would make the thing pay. In the present case, I am bound to say that both ends have been very well catered for. Given a fountain, a military band, and some machinery in motion, and you can generally get a good crowd. When to this you add such attractions as Mr. Gladstone's silver axe, and the bark shell of one of the "big trees" from California, into which two score of people can go at once, and a great lot of curious things beside, of course the populace will support you. I have just discovered and described, for the benefit of needy people, how it is possible to get to the Exhibition free of cost. An enterprising maker of essence of coffee has a stand wherein those neat American paper boxes, sample bottles, are piled up each with a request to "try this sample." On the box it is mentioned that the bottle contains one-tenth of what is given in a shilling bottle, so that a person has only to pass the stand ten times and "try a sample" each time, and then he can leave the place with essence of coffee to the full value of his admission money and thus see all the Exhibition for nothing! Curiously enough, this is the only edible thing given away, for though you can get lots of samples of Californian red-wood, and German wood pulp paper, and a host of other things, the singularly attractive eatable "free, gratis for nothing" things to be picked up in the Health Exhibition in London are not seen here. I don't think I ever saw a fellow so much sold as the man to whom I first offered to explain the new patent for seeing the Exhibition for nothing. Knowing my Press connection, I think he expected at once to get a free pass to see the show, and his disappointment on learning the details of the coffee trick may be conceived. Even today, what promises to be one of the most valuable and interesting branches of the Exhibition is not in place, namely, that from Japan. Curiosity is a good deal whetted on the subject, for the island Empire of the East asked for a whole transept in the building, 5,400 square feet of floor space, and it is understood that the Japanese hope to astonish us with their collection. In the meantime the Indian Government and other Eastern exhibits form the most attractive part of the show. Colonel Michael, arranged the Indian section, so that one feels certain that the Forest Department has put its best foot foremost, both on the popular and the practical side. The uneducated eye takes in at once the idea of that wonderful sheaf of bamboo poles 85 feet in length—the stock in trade of many homes, and occupying a position not unlike that attributed to Edinburgh ale of being "meat, drink and clothing." At any rate the bamboo is fuel, housing and many other things to many myriads of people. The natural mind can also run to the contemplation of the model of the Burmese monastry in carved teak, or the beautiful door in cedrus, deodara, or the curious roc's quills or ribs of the Raphia palm, the last not Indian but from Zanzibar. But all those are but the mere fringes and ornaments of a singularly valuable and complete illustration of what India can do in the way of wood production. The Burmese section is very interesting, affording the most artistic exhibit in this department in the shape of a large gong stand in teak, carved in an elaborate foliaginous and zoomorphic design. The plan of shewing the various timbers from India has been much admired, there being a straight cut and a conic cut of each tree in the same log showing the grain all the three ways—and in most cases both polished and rough. This to the practical man shows at once the value of a wood in grain, &c., and how it stands a cross cut. The principal made-up exhibits of wood in the Indian section are those sent from the Forest Department of the Andaman and Nicobar Islands. A magnificent slab of the poon tree here attracts attention, showing a wood capable of use for many purposes and hitherto unknown here. The beautiful "padowk" wood, running in some examples to a striking crimson hue, is not so strange, for I observe it amongst the Royal Arsenal exhibits as a wood not unknown in use there. But it has not come before us commercially, and a fine mantle piece, a railway carriage door, tables, wheels, and other articles show it in use and in some cases in combination with the fine white "thingan" or the pleasant greenery-yellery, walnut-like wood yclept "chûgalam." A table of the last named, with turned legs of padowk and struts of the curious black and grey "marble wood" struck me as quite too fine as an "occasional table." If those woods are easily wrought they present to our cabinet makers and furniture artistes infinite possibilities of colour which the woods in ordinary use, mahogany, walnut, and oak, do not offer. To let off the practical part with one touch of nature, several palm trees in tubs have been brought in; and right at the top of the transept where India is located, there is the fountain surrounded with shrubs and

flowers, so that upon the whole this is not only one of the most interesting but one of the prettiest bits of the Exhibision.

From the opposite end of the world, the California Red Wood Company makes itself seen, offering the gigantic slabs of the *sequoia*, which seems so to delight carpenters by their freedom from knots. It is a purely soft wood, and not calculated for flooring I should say. But for panelling it is admirable, rich and warm in colour and easy to work, and one of the chief rooms in the new Conservative Club here has been done with it There is a very chaste chimney piece of this wood shown, in which it is seen how the closer grained parts can be turned and carved as pillars while the opener parts suit for flat treatmen. This exhibit is left almost in its natural state, being slightly waxed, and looks as strong as oak, while it is equally effective Choice "burs" of the wood are shewn in panels, and in various ways the merits of this recent importation are displayed. From South America, British Guiana makes an extensive exhibit, and here, too, the practical man sees openings which doubtless will modify our ideas of furniture some day. The conservative spirit of the British workman—not politically, but in his trade—must give way to the lessons of such a collection as is here, and instead of a mere choice of ash or beech in light woods, and mahogany or walnut in dark, we shall have examples of furniture in many tones and combinations of colours. In fact I have started the idea of getting a harlequin set of chairs just as we used to see sets of tea cups where each was different in colour We might see a red-wood chair from California, a white "thingan" chair from Andaman, a British oak, a Scottish pine (the Queen shows some excellent white pine furniture) and other woods drawn from every country from China to Peru. I share Sidney Smith's idea as to his breakfast plates; he always bought odd ones, and would say "it was quite a treat to eat off the plate I had this morning." And so I should like, as the result of this exhibition to get a set of chairs, and to sit on one today and another tomorrow.—*Madras Mail.*

AUSTRALIAN BOTANY,

SPECIALLY DESIGNED FOR THE USE OF SCHOOLS; BY W. R. GUILFOYLE, F.L.S., C.M., ROYAL BOTANICAL SOCIETY, LONDON, DIRECTOR OF THE MELBOURNE BOTANIC GARDENS, AUTHOR OF THE "A. B. C. OF BOTANY," ETC., ETC.

Mr. Guilfoyle has sent us a copy of the second edition of his useful and well-got up little work The frontispiece is an engraving from a sketch of Australian vegetation by the author, a noble Moreton Bay Fig (*Ficus macrophyll'a*) occupying the foreground, with eucalyptus, palms, &c., as accessories The table of contents will give some idea of the scope of the work:—

CONTENTS.—Lesson.—I.—Seeds, II.—Structure of Plants. III.—Roots, IV.—Stems, V.—Leaves. VI.—Flowers. VII.—Fruits. VIII.—Acotyledous. IX.—Systematic Botany. Simple Directions for the Collection and Preservation of Specimen Plants. Examination or Dissection of Flowers and Fruits. Australian Vegetation. Glossary. Principal Plants of Economic Value.—No. 1. Plants used as Food, yielding Esculent Roots, Leaves, etc. No. 2. Plants yielding Edible Fruits, Nuts, etc. No. 3. Spice and Condiment Plants. No. 4. Medicinal Plants. No. 5. Plants yielding Gums, Resins, and Balsams. No. 6. Fibre Plants used in the Manufacture of Clothing, Cordage, and Paper. No. 7. Plants used for Dyeing. No. 8. Principal Timber Trees of Commerce. Wild Plants found around Melbourne, and common in New South Wales, Queensland, South Australia, and Tasmania. Natural orders of Plants represented in Australia. Botanical Index.

The preliminary and general matter has the merit of great simplicity and clearness, but, in selecting extracts, we are, of course, attracted to the portion of the book which deals with Australian vegetation:—

Foremost in point of beauty for floral effect is the *Eucalyptus ficifolia* which bears large bunches of bright scarlet flowers. It is a native of Brokes Inlet, Western Australia. This magnificent plant, when in full bloom, is one of the most gorgeous objects possible to conceive. Seen in the distance, it appears like masses of fire. A red flowering variety of *E. calophylla*, red gum of Port Gregory, is also very beautiful. The same might be said however of the 'flame tree' (*Sterculia acerifolia*) of Queensland and New South Wales, which, in many parts of those colonies, but especially of the latter, the Illawarra district, for instance, is very plentiful. When met with in the brush-lands, a single specimen presents an almost dazzling effect; but when seen *'en masse'* at a distance, from the mountain slopes, it is indeed a glorious sight. Its splendid display of colour is often enahanced by the refreshing green of the foliage of other trees, and perhaps by a background of far distant mountains suffused with that bluish vapour which renders the scenery peculiary charming.

Acacia.—Pp. 20, 54, 190. See also Wattle, Black Wattle, Golden Wattle, Silver Wattle, and Blackwood of Lightwood (*Acacia melanoxylon*). The genus Acacia comprises some 300 species. The flowers appear in dense, mostly yellow, clusters or racemes, loading the air with a most delicious perfume. The seeds of most of the Acacias require soaking in hot water for some time before sowing, to assist early germination. The tallest growing Australian Acacia is the 'Blackwood' or 'Lightwood,' which often attains a height of sixty or seventy feet. Besides being a highly ornamental tree, the timber is useful for furniture and implements requiring toughness. Many of our Australian species yield a valuable gum almost equal to Gum Arabic.

Australian Bottle-tree.—Sterculia (Brachychiton). (Natural Order, Sterculiaceæ.) Pp. 53, 193.—The generic name of this tree is less known than its common name of Bottle-tree, given to *Sterculia diversifolia* and *Sterculia rupestris* on account of the peculiar shape of their swollen trunks. The bark, when macerated in water, produces a lace-like bast, which has been converted into ropes, cordage, and coarse paper. The Victorian Bottle-tree (*Sterculia diversifolia*) is well known by the aboriginal name of "Kurrajong" in East Gippsland. The natives manufacture fishing lines and nets from the bark. A sweet, gummy, edible substance exists between the inner bark and the wood. In New South Wales it is generally known as the "Kurrajong tree," where it is often felled for stock when pastures fail, and is therefore valuable as a fodder plant. At the Kurrajong Mountains in New South Wales it is called the "Rattle-trap tree," on account of the loud rattling noise made by the long racemes of hard woody seeds, capsules, or pods being brought into contact when shaken by the winds. The roots, bark, young shoots, and foliage are readily eaten by the stock of all kinds, and their mucilaginous contents are no doubt nutritious. The blacks also make use of the pith and roots of this tree as food.

Bangalo Palm.—Seaforthia. (Natural Order, Palmæ.) Pp. 24, 92.—The generic name now most in use is Ptychosperma. This noble plant is unquestionably one of the grandest and most graceful of the Palm tribe. In tropical Australia the indigenous species may be found towering to a height of 100 feet. Their feathered fronds, waving in the breeze, have a magnificent appearance. *Seaforthia elegans* is perhaps the most beautiful of all. *Seaforthia robusta* is found at Illawarra, New South Wales, where it grows to a height of 150 feet. These tall Palms are of great value in landscape gardening where the climate admits of their growth, as by judicious grouping they impart a charming effect to the scenery.

Cabbage Palm.—Livistona (Corypha) Australis. (Natural Order, Palmæ.) Pp. 24, 90.—This magnificent Palm has been found on the borders of the Gippsland, and is therefore the only Victorian representative of its tribe. It is principally met with in the valleys and deep ravines of tropical Australia, where it occasionally attains a height of 120 feet. In Illawarra, also at the Bellenger, Clarence, Richmond, Burnswick, and Tweed Rivers, New South

Wales, it is very common. The young, undeveloped leaves are eaten by the Queensland natives, who term the plant 'Konda.' When fully grown the leaves resemble large fans; they are very tough easily split, and are worked into baskets, hats, and similar articles.

Flame Tree.—Sterculia (Brachychiton) Acerifolia. (Natural Order, Sterculiaceæ.) Pp. 30, 53, 87, 191.—One of the most magnificent trees in existence, bearing a profusion of scarlet coral-like racemes of flowers, and large bright green leaves. The bark, which, like that of most of the tribe, is composed of concentric layers, yields by maceration a lace-like bast of fine texture, which can be converted into cordage, ropes, mats, etc. The tree is found on many parts of the eastern coast of Australia; seldom far inland. In the Illawarra district, fifty or sixty miles south of Sydney, it is very plentiful. Commencing at the Macleay River, it is found in the brush lands of most of the northern rivers of New South Wales—the Bellenger, the Clarence, the Richmond, the Brunswick, and the Tweed. On the banks of some of the Queensland rivers it may occasionally be found. For several weeks during the summer season this tree presents a most gorgeous sight. From the splendour and profuseness of its bloom it derives its common name. At Illawarra the finest specimens occur. When in flower one could imagine portions of the landscape to be on fire. The foliage sheds itself to give room for the profuse inflorescence. The Lasiopetalums (*Velvet-flower*) belong to this order. One of the tallest growing *Lasiopetalum Tepperi*—a most beautiful shrub with pink flowers—attains a height of 5 or 6 feet, and is found at Yorke's Peninsula, South Australia.

Grevillea.—(Natural Order, Proteaceæ.) Pp. 42, 53, 171.—A very large genus, comprising some interesting and beautiful Australian flowering shrubs and trees. Nearly 200 species have been described, all, with one or two exceptions, indigenous to Australia, and two-thirds of that number belong to Victoria. They are chiefly admired and cultivated for their flowers; some of them are of a dwarf heath-like habit; others are trees of a considerable size. The most noticeable is the 'Silky Oak' (*Grevillea robusta*), a grand timber-producing species, bearing large masses of comb-shaped orange flowers. It is a native of New South Wales and Queensland, where on rich alluvial river banks it often attains a height of over 100 feet.

Gum, or Eucalyptus.—(Natural Order, Myrtaceæ.) Pp. 16, 18, 20, 26, 32, 40, 81, 85, 86, 87, 88, 195, 199.—Though it is to be regretted that a more appropriate common name than that of 'Gum tree' was not in the first instance bestowed upon this extensive family, comprising the principal timber and most stately trees of Australia, still the term has now become so widely spread that only partial success could be expected to attend any sudden attempt to alter it. Under its popular name, therefore, each species will be mentioned. The substance which exudes from the tree is known all over the world as 'Kino.' The Tasmanian Blue Gum *Eucalyptus globulus*) is widely known, and is very common in Victoria.* It is a quick-growing tree, attaining in favourable situations a height exceeding 300 feet, and producing very hard and durable wood, in great request for shipbuilding, fencing, railway sleepers, and many other purposes, where toughness and staunchness in the material employed are indispensable. This tree has lately attracted considerable attention from its alleged power of counteracting malaria, and the weight of testimony goes to prove the truth of the statement. From this fact the Blue Gum is known in Southern Europe as the Fever tree. The Red Gum† (*Eucalyptus rostrata*) (the 'Blue Gum' of New South Wales) is common in Victoria and South Australia, and is principally found in low, moist situations. Its wood has been held by experts to be superior even to that of the Tasmanian Blue Gum for durability. The Jarrah (*Eucalyptus marginata*), native of West Australia, Ironbark (*Eucalyptus leucoxylon*), and Karri (*Eucalyptus diversicolor*), are also famed for their splendid timbers, which are valuable, for jetty piles, shipbuilding, etc. The Stringybark (*Eucalyptus macrorrhyncha*) and Messmate (*Eucalyptus obliqua* are two of the tribe most plentiful in Victoria; and though their timber is not very durable, it is largely employed for fence rails, quartering, battens, shingles, palings, etc.; whilst the bark is used for roofing by the settlers, and also converted into pulp for the use of the upholsterer and papermaker. A volatile oil is distilled from Eucalyptus leaves, those of the Blue Gum and Giant Gum of the mountains being principally used for this purpose. The latter tree, it is said, has been known to attain the exceedingly great height of 400 feet, having a diameter approaching 23 feet It is found in its most noble proportions in Gippsland. The Karri of Western Australia rivals the Giant Gum in height. The Alpine Gum (*Eucalyptus alpina*) is a small but well-shaped shrubby specimen of the family, and is very hardy. The Yellow Box (*Eucalyptus melliodora*) is attractive to bees, from the quantity of nectar secreted by its flowers. Under the name Ironbark, four or five species of the Eucalyptus are comprised, the principal of which are *Eucalyptus siderophloio* (New South Wales) and *E. leucoxylon*, common in several of the Australian colonies. In point of beauty, however, as distinguished from the towering height and stately appearance which mark other members of the family, the gorgeous Scarlet Flowering Gum (*Eucalyptus ficifolia*) stands without a rival.* This beautiful tree, a native of Broke's Inlet, Western Australia, is sometimes met with in groups or single specimens on the hill-sides, and frequently in the valleys. Its handsome tufted heads of bright scarlet bloom, in contrast with the dark green of the foliage, renders it a most attractive object in the landscape. There are upwards of 150 species of Eucalyptus confined to Australia and some neighbouring islands, but none are known in New Zealand. For further particulars concerning this genus, see also chapter on 'Australian Vegetation.'

Moreton Bay Pine.—Araucaria Cunninghamii. (Natural Order. Coniferæ.) P. 23.—A magnificent timber tree, frequently met with on the banks of rivers at their confluence with the sea, but often found a considerable distance inland in the colonies of Queensland and New South Wales. Its timber is largely used for flooring-boards, etc. In favorable situations it reaches 200 feet in height. It is of quick, though erratic growth; some times making shoots 8 or 10 feet long during a season, without throwing out lateral branches; at others, branching at a distance of 2 or 3 feet.

Nettle.—Urtica. (Natural Order, Urticeæ.) Pp. 29, 42.—A large genus of plants, principally distinguished for the virulence of the sting caused by their glandular hairs. Some of the species yield beautiful and valuable fibre. The New South Wales Tree Nettle (*Laportea gigas*) grows to a height of 100 feet. The sting from its leaves is so great as to create severe inflammation. Cattle brushing against its branches have been known to run absolutely mad until the pain subsided. The bark of this tree affords a strong fibre, which the natives convert into fishing lines and nets. The Common Nettle (*Urtica dioica*) is a perennial, cosmopolitan weed, being either indigenous or naturalized in most civilized countries.

Sheoak.—Casuarina. (Natural Order, Casuarinæ.) Pp. 21, 55, 205. See also chapter 'Australian Vegetation,' p. 85.—The black, gloomy appearance of these singular trees is familiar to dwellers in the Australian bush, where their leafless branches form one of the most striking features of the landscape. A few kinds only are indigenous to Victoria, *Casuarina suberosa* (erect Sheoak or Victorian Beefwood) being the most common. The shrubby species *Casuarina distyla* and seven others, including *C. quadrivalvis*, are abundantly scattered through Southern Australia. Like many other names given by the earliest settlers, the term oak was given to this genus because

* The 'South Australian Blue Gum' is *Eucalyptus viminalis*, and is common in Victoria, where it is known as the 'Manna Gum."

† The 'Red Gum' of New South Wales, known as such to the earliest settlers, which is by far their best wood for fuel, and the resinous gum of which is used for various purposes, is a species of *Angophora*, and is still one of the commonest 'Gum trees' on the north shore, etc., Sydney.

* There is a scarlet flowering variety of *Eucalyptus calophylla* indigenous to West Australia which is very beautiful, and resembles in many respects the *Eucalyptus ficifolia*, but it is nevertheless quite distinct in colour of blossom and form of seed, though the capsules are almost identical. Young specimens of both may be seen in the Melbourne Botanic Gardens.

when worked up the wood had some resemblance to that of the English oak, and in fact was used like it for staves, for buckets, kegs, tubs, &c. The species most common around Melbourne is known in New South Wales as 'Forest Oak.'

Silky Oak.—See 'Grevillea Robusta," pp. 53, 125.—The most noticeable of the numerous species of this genus known in Australia. It is a grand timber tree, bearing large masses of comb-shaped, highly-perfumed yellow or orange coloured flowers. It is a native of Northern New South Wales and Queensland, found on rich alluvial river banks, where it often attains to a height of 100 feet. It is considered the best Australian stavewood.

TREE FERN.—(Natural Order, Filices.) Pp. 19, 20, 57, 58.—These noble representatives of the fern tribe form a special feature in Australian and New Zealand vegetation, often attaining a height exceeding 80 feet. *Dicksonia antarctica* and *Alsophia australis* are the two most frequently met with in Victoria; the former is the pride of our fern gullies, and is found only in the most shady and well-watered localities. The latter is often encountered growing on mountain-tops, its feathery fronds waving in the breeze. It is known as the mountain Tree Fern and Umbrella Fern.

TRAVANCORE.

From the report on the administration of this native state which has been sent to us, we learn that the population shown by the late census was 2,400,000. The true number is probably over 2½ millions. From the table of exports we notice that copperah and coir are the great staples, cardamoms occupying a very secondary place. There are several references to the abolition of the Indian import duties having given products from Ceylon an advantage in the Calcutta market over similar products grown in Travancore. We quote as follows :—

The value of the exports by sea during the year was less by R1,45,953 than in the previous year, though if we include the exports by backwater also, the result is a considerable increase. Confining ourselves, however, to the trade by sea direct from the Travancore ports, we see a falling off of R3,45,563 in one article namely copra. This decline occurs in the export both to Bombay and Calcutta, but is striking in the case of the latter as shown by the following figures :—

	Bombay.	Calcutta.	All other places.	Total export by sea.
	R.	R.	R.	R.
1,054...	6,58,573	2,12,184	35,661	9,06,418
1,055...	7,97,106	2,27,229	1,541	10,25,876
1,056...	7,85,894	4,37,715	15,159	12,38,768
1,057...	8,13,567	1,80,006	18,385	10,11,958
1,058...	6,11,765	44,940	9,690	6,66,395

The trade with Calcutta in this one article has thus fallen to less than one-fourth of what it was in the previous year, or, if we compare it with 1 056, to one-tenth. This declension is attributed by the Commercial Agent to the abolition of the duty levied at Calcutta up to March 1878, i.e., the Malabar year 1,054 on Ceylon and Nicobar copra, but as the exports of 1,055 and 1,056 were apparently unaffected by this cause, but on the contrary rose considerably, and as it is reasonable to suppose that the unfavorable seasons of the last few years must, by diminishing production have had something to do with the diminished exports of 1057 and 1058, it is perhaps premature to conclude that the falling off in the diminished exports of copra to Calcutta is due altogether to the abolition of the duty mentioned by Mr. Rohde. It may be that for some time after the abolition of duty, Travancore copra retained its hold on the market from its superior quality, but that it has since lost its ground owing to the cheaper article taking its place. But whatever the cause, the course of the trade in this article will need to be carefully watched.

The abolition of the export duties in Travancore will doubtless be the proper step to take to free the trade of the State from the advantages under which it now undoubtedly labors and to enable it to compete fairly with other parts of the country, but though on financial grounds it is not possible to do this immediately when we have a Revenue Survey and Settlement on hand which is entailing a large annual expenditure, still the results of those operations will be carefully watched in view to applying a large share of the increase of revenue expected therefrom towards freeing trade as far as possible.

Coconut Oil.—There is an increase of R29,468 in the total export of this article. The bulk of the increase occurs in the quantity carried by backwater. The reduction of the tariff value of this article from R15 to R14, which was made in the year under report, has doubtless led to a large conversion of copra into oil in the country itself.

Coir and fibre show an increase of R2,58,447 in the total export. The increasing demand for this article in America, and the more economical methods adopted in its manipulation in consequence of an increasing appreciation of its value, have led to a healthy development of the coir-spinnig and coir-matting industry in the country. The following figures show how steady the progress of this trade has been during the last five years :—

Years.	Value. R.
1,054 ...	12,48,300
1,055 ...	13,82,100
1,056 ...	12,60,000
1,057 ...	15,12,300
1,658 ...	17,70,747

There was a decrease of R20,216 in the entire trade in this commodity. If we take the total export trade in copra, coconut oil, coir, coir fibre and coconuts,—all the produce of the cocoa, which forms the staple wealth of the country and constitutes 54 per cent of the whole export trade—we find we have exported R127,857 worth less in 1046 than in 1058.

Areca shows a falling off of R52,907 in the total export. The greater portion of the decrease (R44,725) is in the export by land. This article is chiefly sent to the adjoining districts of Tinnevelly and Madura. The export by sea of this article has dwindled down to almost nothing.

The cause assigned by the Commercial Agent is the abolition of the British Indian import duty on areca in March 1882 *i.e.* about the middle of 1057. But the decline commenced much earlier. The subject needs closer investigation.

Coffee.—This important article shows perhaps the largest falling off, being R4,46,065 or 53 per cent less compared with the previous year. The continued depression of this once thriving industry accounts for this result. The direction of the trade by sea in this article is shown below :—

Places.	1057. Quantity. Cwts.	1057. Value. R.	1058. Quantity. Cwts.	1058. Value. R.
British India.				
Bombay... ...	83	1,703	3,077	62,642
Calcutta... ...	194	3,591	184	3,758
All other places ...	619	13,043	99	2,029
Total...	896	18,337	3,360	68,429
Foreign Countries.	Cwts.	R.	Cwts.	R.
London ...	20,700	3,69,346	7,748	1,57,736
New York ...	,,	,,	,,	,,
Colombo ...	5,654	1,65,420	1,697	29,020
All other places ...	168	2,900	7	147
Total...	26,522	5,37,736	9,452	1,86,908
Grand total...	27,418	5,56,073	12,812	2 55,337

Dry Ginger.—The total export under this head was higher than of the year preceding by R61,161. The article was principally sent to Bombay, New York and Jeddah.

Palmyrah jaggery.—In this also there is an increase of R64,945. It is produced in South Travancore and being of superior quality is taken largely to the Tinnevelly district. A demand has now sprung up for it in Europe where the jaggery is said to be converted into an inferior kind of sugar.

Salt fish.—The entire trade shows an increase of R23,336 Colombo is the principal consumer.

Pepper.—There is a large increase in the total export of this—another staple article of export—amounting to R1,61,714. The season of the last year was marked by

abundant rains in Travancore and increased production.

Cardamoms.—The outturn of the crop last year was even worse than in the preceding year and consequently the export was less.

The entire export of this article was by sea and Bombay had by far the largest share of it. Calcutta and New York imported smaller quantities.

Colachel, as a place of trade, has unfortunately gone down with the declension of the coffee industry. The Scottish Indian Company who established themselves there several years ago have closed their business and abandoned Colachel. But it is satisfactory that Quilon is increasing in importance.

REPORT OF THE CALCUTTA TEA SYNDICATE.

Since their last circular, dated 26th April, was issued, the Committee have received the following advices from the Agents of the Syndicate, which they think will be of interest to shippers to the markets in question.

Australia.—Writing on the 2nd June, Messrs. James Henty & Co. say they regret to observe that the total exports of Indian teas to the whole of Australasia for the season of 1883-84 amounted only to 340,613 lb. against 2,699,242 lb. in the previous year. On the 24th April 1882 they estimated the probable yearly quantity of Indian tea that could be consumed by their Colony of Victoria alone at 2½ million lb., and they state that during the season of 1882-83 about 2½ million lb. weight of Indian tea did actually go into the hands of the trade, and by the 24th September 1883 importers and speculators held no stocks. They attribute the low prices obtained entirely to the undesirable quality of the greater part of the tea sent to their market, which they describe as coarse, stalky, and broken teas, with common poor liquors, packed in rough heavy chests, too large for the general requirements, and which compared unfavourably with the neat even boxes from China. The Agents are convinced that had more attention been paid to the selection and packing of the tea, the results would have been as favorable as they had been anticipated.

In the beginning of its operations with Australia, when the Syndicate was almost the only shipper, neat half-chests containing even desirable teas only were shipped, and it was upon a continuance of these teas and boxes that the Agents based their calculations. It is to be regretted that, in accordance with a general wish, this system of hulking and repacking was abandoned, and that all teas sent to the Syndicate were shipped in original chests, if sufficiently sound, in the hope that after a time the trade would get accustomed to them.

It would appear from the Agent's advices that the estimate of 2½ million lb. as the probable yearly consumption of Indian tea in Victoria is not too high, and that fair prices will probably be realized, provided only suitable kinds of tea are sent forward, and the packages are of the proper weight.

They consider it is not advisable to send whole chests, as the enquiry for them is confined entirely to a few blenders whose wants are soon satisfied. Half-chests containing from 28 to 40 lb. net are the kind of packages universally liked throughout the colonies, and packed in this style, Indian teas are most likely to reach the consumer without an admixture of China tea. Half-chests of 50 lb. net are also freely taken by the the Trade, but the weight is too heavy for the class of consumers who buy a half-chest at a time for home use.

Tins of 20 lb. net, quarter chests of the same net weight, and boxes containing 10 to 12 lb. net are well suited to popularize Indian teas, but only suitable kinds for drinking by themselves should be offered in these packages.

The size of breaks is a very important matter, as the dealers do not care to look at small lots consisting of less than 20 half-chests. Many of these small breaks were shipped during the season of 1882-83, and had to be sold privately at lower prices than the teas would have realized if put up to auction in breaks of 30 to 50 half-chests. The agents recommend that teas costing not over 8 annas per lb. should be shipped in breaks of about 50 half-chests, and that finer kinds should be in breaks of about 25 half-chests.

The Committee would request your special attention to to the following paragraph from their Agent's letter as to the class of tea most suitable for the Melbourne market:—

"Darjeeling teas of all descriptions especially those with sweet fruity liquor."

"Pekoes of all kinds with even wiry leaf and a fair amount of tip."

"Pekoe Souchongs with not too large leaf, but with red infusion, and Broken Teas with deep red infusion.

"Broken Pekoes are liked but rarely realize a high price.

"Dehra Doons are not in favour."

The Agents further say—"You cannot go far wrong with even leaf or small even broken leaf, but large leaf is only suitable to blenders who are few in number."

They propose to make quick sales and to reduce all charges as low as possible.

America.—Advices received up to the date of the Committee's last circular of the 26th April, quoted the New York Tea market very strong owing to the moderate visible supply. This state of things continued until the middle of March but soon afterwards a gradual decline set in, and prices fell from 30 to 50 per cent. above those current in the early part of December to only 16 to 15 per cent. above those values. The Agents write that, during the excitement which prevailed in their market in March, a few Indian teas found their way over from England, and were sold at auction during April at about London prices, though in some cases at rather less. Notwithstanding these sales there had been a fair demand for Indian teas privately, and a moderate quantity of black leaf could have been disposed of on satisfactory terms.

The Committee have not yet had any particulars of the sale of the small purchase made on account of the Syndicate, which was referred to in their last circular.

Northern Europe.—The Committee have as yet received only one parcel of 40 half-chests of New Season's tea for shipment to Amsterdam, so it has been thought desirable for the Syndicate to make a small purchase for this market also.

In his Report on the Indian Department of the Amsterdam International Exhibition which has lately been issued, Mr. J. R. Reyle, the Executive Commissioner for the Government of India, writes as follows:—

The steps taken by the Calcutta Tea Syndicate in sending over with the assistance of the Government of India, a valuable series of samples of tea for exhibition, as well as in fitting up a tea-room where native servants supplied cups of tea gratis to all comers, had the wished for effect of creating a demand for Indian tea. The mere idea of any refreshment being given without any charge appeared so strange to Dutch notions that visitors crowded to the tea-room daily, and could scarcely believe that no charge would be made. Some of the better class of visitors at first objected to placing themselves under any obligation by drinking tea without payment, but this feeling soon wore off, and the tea-room was thronged during the hour and a half to which it was found necessary to restrict the distribution. On an average about 500 cups of tea were given away daily, or more than 40,000 cups during the whole time of the Exhibition.

Shortly after the opening of the tea-room, seeing that no practical result was likely to ensue from the mere giving away cups of tea, I obtained the consent of the Tea Syndicate to the sale of ½ lb. and I lb. packets which were made up in the Exhibition by the native servants. For these there was at once a brisk demand, and although the sale was only carried on during the time tea was served, and had frequently to be temporarily suspended while awaiting the arrival of further supplies from London, about 2,700 of the packets were sold during the Exhibition.

Unfortunately it was only in the power of the Indian Department of the Exhibition to create a demand for tea, but it was unable to create also a constant supply."

The Committee would beg to invite your very particular attention to the above extract from Mr. Royle's report, and they trust that as the demand has been created by the Exhibition, and has been kept alive by the small shipments which the Syndicate has been able to make hitherto, it will not be allowed to die out in consequence of a failure of contributions of tea on the part of the members of the Syndicate. The funds of the Syndicate are limited, so the Committee cannot do much in the way of purchasing tea for shipment to new markets, but must depend largely on the support of proprietors and agents of gardens.

The Committee would now ask you to be good enough to fill up the accompanying form stating the quantity of the present season's tea you are prepared to make over to the Syndicate for shipment. The Committee propose that their total consignments to Melbourne should not exceed 100,000 lb. during the year, so as not to interfere in any way with private shippers. For America, as there appears to be little trade in Indian tea beyond what passes through the Syndicate, the Committee are anxious to have full supplies, in order to keep up the demand which has already been established. For Amsterdam the Committee would like to have liberal contributions so that regular shipment might be kept up.

The total shipments from all sources since the 1st May 1884 have been—

To AUSTRALIA.	To AMERICA.	To NORTHERN EUROPE.
11,191 lb.	16,724 lb.	3,946 lb.

So it would appear that much more requires to be done to prevent these markets being lost as outlets for a large portion of the increasing crops of Indian tea.

WOOD USED FOR TEA BOXES.

(From the *Indigo and Tea Planters' Gazette.*)

In our last issue we reproduced the entire text of Dr. Watt's memorandum on the woods used for tea boxes. In this issue we give in its entirety the very valuable letter of Mr. P. Playfair, embodying Dr. Voelcker's minute. We need scarcely say that our own views entirely coincide with those of Dr. Voelcker. The subject is dealt with in more detail in our editorial columns,

The memorandum by Dr. Geo. Watt upon woods suitable for tea boxes, which was published on 26th instant for general information, is interesting in so far as it offers a new and probably an original opinion upon the cause of the damage lately sustained by Indian teas, and which is generally attributed to the action of juices in certain woods coming into contact with the lead lining in which the tea is encased. Dr. Watt suggests that it may be the tea itself which corrodes the metal and not the wood, and the opinion is, as he states, at "variance with the popular outcry." As it differs with a professional opinion which I obtained in London last year, the premises assumed by Dr. Watt being also at a variance with the circumstances on which the opinion was formed, I venture to produce this.

Two invoices of 726 cases of tea manufactured during Oct. and Nov. 1882, were shipped direct from the factory arriving at London *via* the Canal in April, 1883, and on being sampled were found to have a "peculiar cheesy-like smell." On examination, the surface of the lead next the wood forming the lids to the boxes, was found to be covered with a whitish and, in some cases, a yellowish kind of mould, while the surface against the tea was quite bright and clear; the lead was perforated, and in instances completely corroded. This injury only existed on the tops, the sides and bottoms of the wood and lead casing being unaffected and perfectly sound; and not only so, but in many instances the lead was corroded under only one or two of the several pieces of which the lids were composed, the rest being sound. The wood and lead had a very pronounced and disagreeable smell which had been transmitted to the tea. There was no external sign of damp, and the tea was not damaged in the usual sense of the word; without the smell it would have been in good condition. The tea was turned out on the floor of the warehouse; and pending investigation and examination, it was left exposed for a few days, during which the objectionable smell toned down and left the tea so rapidly that only 64 out of the 726 were eventually condemned as "peculiar," and were disposed of as such, although the whole invoice on arrival was tainted. I inspected and sampled the tea in the London warehouse, and extract the above remarks from notes and records I retained.

Samples of the wood, lead, and tea were submitted to Dr. Augustus Voelcker of London, and the following is his report:—

"Having completed the examination of the specimens of wood and lead from various tea chests which you received from India, I have now the pleasure of reporting to you the results of my investigation."

"The several specimens were marked Nos. 1,634, 1,731, 1,737, 1,742, 1,748,—wood from the lids of the tea chests and leads."

"Nos. 2,199, 2,254, 2,304,—wood and lead from the bottom of the chests."

"No. 2,038,—wood and lead from a tea chest from another garden apparently sound."

"The lead taken from the top of the chests was more or less corroded in every case, whilst the lead from the bottom of the tea chests was only slightly attacked at the jambs, which may be due to the solder; otherwise the lead from the bottom of the chests was sound apparently, and no perceptible corrosion could be noticed in the case of No. 2,038."

"The examination of the corroded leads showed me that the corroded leads are covered in the worst specimen with a white heavy powder which strongly effervesces with acids, and proved to be a mixture of oxide and carbonate of lead, or in the main white lead. Besides this, I found soluble lead salts in the corroded leads. The presence of lead and acetic or analogous volatile organic acid can be readily shown when the corroded leads are washed with distilled water."

"The following tabulated results may give some idea of the relative degree of corrosion to which the leads were subject:—

	Lead in solution *in water.*	Carbonate of lead *insoluble in water.*
From lead nearest to the lid of the chests.	No. 1634.—Strong lead reaction.	Slightly covered with carbonate of lead.
	„ 1731.—Very much corroded.	Strong effervescence with acid, much white lead present.
	„ 1737.—Very much corroded.	Ditto.
	„ 1742.—Worst damaged lead,	
	not much lead in solution.	Mostly carbonate of lead.
	„ 1748.—Similar in all respects to 1742.	

No. 2,199.—Only slightly corroded on jambs, and showing only slight indications of soluble lead salts.

Nos. 2,254 and 2,304.—The same as No. 2,199.

Lead from a chest from another garden.—No. 2,038.—Lead sound."

"The corrosion of the lead unquestionably is due to the attack of acetic and other volatile organic acids which dissolve the surface and sometimes eat holes into the leads, and the subsequent formation of white lead (carbonate of lead) by the carbonic acid of the air."

"Considering the fact that the surfaces of the leads which are in contact with the tea were quite bright and sound whilst the under surfaces in contact with the wood were all more or less corroded, it appears to me that, in all probability, green or unripe wood has been employed in making the tea chests."

"Such wood is known to generate, in a somewhat warm locality, acetic and analogous organic acids which act upon lead."

"With the exception of the woods from the bottom of chests marked No. 2,199 and No. 2,038, which are very similar in their character and lighter and much more porous than the wood from the lids, all the specimens of wood were very similar in appearance. All were tough, hard, and heavy woods; some had a decidedly disagreable smell; others had only a faint smell."

"On distillation with water I got in some cases most disagreeable smelling products; and by extracting the worst and strongest smelling woods with ether, I obtained oily and resinous matter in appreciable quantities, having an intensely disagreeable smell, reminding one of a mixture of rancid butter and rotten cheese."

"The oily, and resinous matter, in short, stank, and had a fishy smell."

"The following tabular statement may not be without interest."

"Wood from a number of tea chests from India:—

Character of the Wood.	*Smell.*	*Distillate.*
No. 1634.—A hard, tough, heavy wood	Bad	Smelt very disagreeably
„ 1731.—Similar to No. 1634	Very bad	Strong smell of butyric acid
„ 1737.—Hard wood, like No. 1634	Only faint smell	

No. 1748.—Smiliar to No. 1737	Very bad smell	Smel tvery strong
,, 1634.—Apparently bad the worst smell		
,, 2199.—Much lighter wood, and more porous than the preceding sample	No smell	
,, 2254.—A dense, heavy wood	No smell	
,, 2803.—Similar to No. 2254	No smell	
,, 2031.—A porous light wood, very much like No. 2199	No smell	

"It appears thus that some of the woods have a strongly-marked fishy smell, which no doubt, will be readily communicated to the tea."

"The peculiar odour I found passed off rapidly on exposure to the air, and I would therefore suggest to you to spread out for a short time the tea which, in my judgment, has taken up a more or less peculiar and unpleasant flavour from the wood, and then to re-pack in leads and chests."

"Whilst I have no doubt that the peculiarly nasty smell of some of the specimens of wood which you sent me for examination has been communicated to the tea, I am bound to that I cannot detect any difference in the two samples of tea which you sent me with the wood from the chest."

It was subsequently ascertained that owing to a large increase to the season's crop, the supply of box lids had run short at the Factory, and green wood had to be employed for lids. This was said to be wild mango wood; and unfortunately, in making up the lids, seasoned and unseasoned shooks were used indiscriminately, explaining, perhaps, the appearance of corrosion under only certain sections of the lids.

The above does not go to support Dr. Watt's suggestion that "it is the tea itself which corrodes the metal, and not the wood: nor do the circumstances support statements in the following paragraphs of the memorandum. Dr. Watt writes:—

(*a*) "That tea may be completely destroyed, and yet upon the most careful scrutiny not a single opening can be detected in the lead, and that it is obvious that when the lead is corroded through or perforated, any injurious influence which the tinning might exert upon the tea could not take place."

The above evidence, and my experience in other instances, so far show that the tea is only tainted when the lead is pierced, and that the strength of the flavour imparted to the tea is in proportion to the degree of corrosion on the lead.

(*b*) "I have not seen a lead lining completely perforated; but it is curious that the fact that the action seems to commence on the inside of the lead, instead of on the outside, or on the surface in contact with the wood (the supposed acid influence which decomposes the metal), has not been apparently observed."

As stated above, the surface of the lead next the tea was bright and clear; the corrosion evidently began on the surface next the wood.

(*c*) "It is some time now since the action of iron nails, screws, &c., was perceived by the planters to be injurious, and in his tables and machinery these are, by the experienced planter, carefully covered over or protected."

It was found that the iron discoloured the golden tips or flower of the leaf, detracting from the appearance and affecting the market value of the tea; but this did not prejudice the liquor or affect the flavour.

If damage arises from the action of tea upon lead, why has it not occurred until now? Why did it not occur when teas were "sun dried," and, as we know, often imperfectly cured? And why is it not noticeable in teas packed in teak, cedar, and toon woods? On the other hand, it may only now occur in connection with Indian woods, as timber is becoming scarcer and dear, and contractors may have been tempted to deliver inferior and unseasoned woods. Dr. Watt appears to consider that the system of manufacture may be at fault, adding "the introduction of advanced machinery to lessen the expense of labour would seem to augment the climatic influence upon the manufactured article." But I think it has been proved beyond dispute that with the assistance of machinery, a tea of improved quality and a more marketable commodity is produced. By the use of machinery fermentation can be arrested in a uniform manner with regularity, and a fresh aroma ("nose") and crisp feel, two qualities having an important market value, are imparted to the tea. If instances do occur showing that some machine-dried teas have reached the market limp and faulty, the workman, and not his tools will probably be the secret of the defect, or it may be found that the planter labours under the disadvantage of inadequate accommodation or insufficient drying machinery, or both.

Dr. Watt's experiments, with woods and leads, described in paragraph 4, were conducted in Calcutta during the cold weather; and although the timber was damped, it may be supposed that, at this season of the year, it would not resemble the condition of wood at an Assam tea factory during the rains, when, after a few days' exposure, the original colour is at times hardly discernible.

I do not in any way pretend, Sir, to solve the question, and merely communicate the above particulars as the result of observation. It is a subject of considerable importance, and the industry is indebted to Dr. Watt for having taken it up.—I am, &c.,

P. PLAYFAIR.

5, Lyon's Range, Calcutta, July 29th, 1884.

IMPORTATION OF TOBACCO FROM SUMATRA AND JAVA DURING 1873-1882.

The important extent of imports of tobacco from Sumatra and Java during the last ten years, appears clearly from a couple of statistic statements appended to the interesting "*Tabaksbericht. Overzicht* 1883" issued by Messrs. P. de Vries & Son, Brokers at Amsterdam.

The first Table shows the crop in the various sections of Sumatra: Deli, Lankat, Serdang, Benkalis, Edi, etc., in the following totals:—

	Packages.	Average c. cents per ½ Kilo, about	Value in guilders about
1873 ...	9,238 ...	182 ...	2½ million.
1874 ...	12,811 ...	154 ...	3 ,,
1875 ...	15,147 ...	172 ...	3½ ,,
1876 ...	28,947 ...	156 ...	6¼ ,,
1877 ...	36,167 ...	128 ...	6½ ,,
1878 ...	48,155 ...	126 ...	9 ,,
1879 ...	57,544 ...	118 ...	10½ ,,
1880 ...	64,965 ...	113 ...	11¾ ,,
1881 ...	82,356 ...	115½ ...	14¼ ,,
1882 ...	102,032 ...	137 ...	21 ,,

Of the different Residencies of Java we find in the second Table the following totals:—

1873 ...	240,006 ...	59 ...	22½ million.
1874 ...	179,328 ...	78½ ...	23 ,,
1875 ...	182,177 ...	50 ...	14 ,,
1876 ...	192,143 ...	54 ...	16½ ,,
1877 ...	146,576 ...	32 ...	8 ,,
1878 ...	159,430 ...	56 ...	14¾ ,,
1879 ...	50,220 ...	66 ...	5½ ,,
1880 ...	150,502 ...	41 ...	10 ,,
1881 ...	196,462 ...	27 ...	9 ,,
1882 ...	71,434 ...	30½ ...	2½ ,,

Since a number of years—write Messrs. P. de Vries & Son—there was not so small a crop of leaf-tobacco as that of 82. And no wonder! The heavy losses, suffered by most of the concerns of late years by the decline of prices of Java *dekblad* at the European markets, had for result that only a few of them continued to devote their attention to the article, many entirely relinquished the culture, and the rest restricted it considerably. Those, who in Java continued to devote their feare and enterprise to this article during 1882, have had no reason to regret it.

With regard to the duty on tobacco of ten cents per kilogram, as proposed by Government, the brokers note, that for sure no one will assert that this duty will do much harm to the consumer; though for many, in our country, tobacco belongs to the articles of daily consumption, yet it cannot be counted among the first necessaries of life, yet it is feared that an increase of duty, whether in the form of import duty or of excise, may have most prejudicial consequences for the manufacture and the culture in Netherland. A main requisite for the tobacco-trade and manufacture is a free action, with the least possible fiscal interference; by this Bremen and Hamburg have prospered in both; whereas London and Liverpool, by the high duties and consequent drawbacks, are of very slight import in the Tobacco trade of the world.—*Indian Mercury.*

THE PRICE OF CAMPHOR.

The price of gum camphor has been steadily declining for some time, but latterly the price has dropped quite rapidly, and the causes leading thereto are interesting. The extreme depression in the labor markets in Japan has for some time been a source of anxiety to the government, and at length some of the restrictions laid on the camphor industry was relaxed, so that some of the idle labor could be utilized in the camphor forests and hereby relieve the suffering of the people. A large number of laborers have availed themselves of the opportunity thus afforded to gain a livelihood, and as the wages paid are very small, the cost of producing crude camphor has latterly been considerably reduced, while the output has largely increased. The consequence has been a steady and rapid decline in the price of the gum until the present time when it is lower than ever before known. The lower price has created an increased demand, though this is largely of a speculative character, as it is well known the present policy of wholesale destruction of the camphor trees cannot go on indefinitely and a reaction must sooner or later set in. For some time past the trees have been felled without replanting, and in some sections nearly all the trees have been cut, and the laborers have been compelled to go farther into the interior to find trees of mature growth. This reckless destruction, although giving temporary relief to the unemployed, will bring future want. The camphor tree is of a slow growth, it requiring several hundred years for them to acquire full size. When the reaction sets in, therefore, we may expect higher prices than have prevailed prior to the adoption of the present suicidal policy. The steadily downward course of the market has made the business of refining and selling camphor unprofitable for some time, as it takes several months from the time of purchase before the refined can be placed on the market here, and the drop between the time of purchase and sale has for some time been sufficient to wipe out the margin of profit, while latterly the market has ruled so low that refiners have suffered losses. A reaction, however, must set in as the wholesale destruction of the trees cannot go on indefinitely, and when the camphor forests are decimated, the probabilities are that higher prices will prevail than before the price fell, and wise operators are taking advantage of the present situation.—*Independent Journal.*

TROPICAL ECONOMIC PLANTS.

We are favoured by "E. B. C." with the following interesting paper:—

A few rough notes of practical experience with economic plants in Queensland may not be uninteresting to you. If so, I herewith place them at your disposal. Supposing we make a start about sixteen months ago with cinchona (*Cinchona robusta* Hybr.). It being then the head of summer, our first and second trials were almost a complete failure owing to insufficient protection from the clear bright atmosphere and high temperature; later on, however, on a third trial we succeeded to get a batch of fine healthy strong plants which stood the test of winter well—sturdy, hardy plants they were—and in the early spring months we had a week or two of fine calm warm weather, when, with copious watering and forcing, we got them into rapid growth, with great expectations of a grand success; but, unfortunately, our not knowing the Queensland weather and climate, round shifted the wind to the south-east with sharp, piercing, cold sleety showers, checking growth and bringing stagnation and gangrene among our otherwise healthy growing young plants, whereby they damped and died off by thousands. However, we got a few through. Some of these we gave away to friends, others we planted out in the open. During summer they made but little progress, but now since the wet season set in they have exceeded our expectations, leaving not a doubt that cinchona bark cultivation will in the future become one of Queensland's best industries to the planter and farmer, especially on the eastern slopes of the coast ranges where soil and climate are in many instances most suitable for its cultivation.

Divi Divi may also be included to become of good commercial value yet to Queensland; they make a fine show for success, are hardy and soon establish themselves, grow luxuriantly in any position; from seed there need not be one failure; the climate, soil, &c., suit them to perfection, and they make rapid growth, making handsome trees near a house.

Indiarubbers—Hevea, Ceará, and the Landolphias—are also pretty sure to become a source of certain profit and value to the planters. Ceará plants grown from seed sown four and five months ago are now 4 ft. and 5 ft. high, with a stem 5 in. and 6 in. in circumference a foot from the ground; indeed, they could not have done better. They have an unusually hardy strength of stem, and, from a light cut, sap of good consistency flowed freely. Surely these are in the future to be of great commercial value to the colony; their growth is superior to anything of this kind I have ever seen in India.

Coffee, of course, is an established fact in Queensland; it only requires proper cultivation and cheap labour to make it pay handsomely. The Liberian variety will be the best for the more northern part of the colony where the plough can be worked—*i.e.*, sandy-loamy flats—intersected with cacao.

Timber trees also are worthy of planting. Teak and mahogany grow rapidly—we have some growing at the rate of 1 ft. per month. We have also a very fine shade tree. "Inggah-samy,"* which would be invaluable for shade to cattle; it grows freely, and attains a great height, with fine spreading branches. Its leaves droop in a similar manner to those of the sensitive plant during rain; otherwise, in sunshine, they give a fine open shade, and the tree is worthy of attention to squatters and farmers, for its fruit is a bean which cattle are very fond of and fatten well on it.—*Queenslander.*

GRUNDRISS DER PHARMACOGKNOSIE.

VON F. A. FLUECKIGER. †

The object of this little work appears to be to meet the need of medical and pharmaceutical students for such an elementary book on materia medica and pharmacognosy as shall contain all the useful information which it is imperative for them to know and remember, but shall exclude such matter as is only valuable for reference. It is of course intended for those to whom the German Pharmacopœia is the standard text-book, and consequently a number of drugs not commonly met with in English pharmacies are described in its pages. Besides those occurring in the German but not in the British Pharmacopœia, a number of drugs which are of recent introduction, such as cola nuts, coca, curare, gelsemium, quebracho, etc., receive a full share of attention. The classification adopted in the 'Grundriss' differs from that of the larger work by the same author, 'Pharmakognosie der Pflanzenreiches,' in the drugs being arranged not according to their nature, but according to the natural orders to which they respectively belong. The awkwardness of finding the root of aconite, for instance, in one part of the same volume and the leaf in another part is thus avoided. In the present volume the cryptogams are placed first, then follow the phanerogams, and lastly the products derived from the animal kingdom. The classification of the phanerogams is not that followed in Great Britain, the dicotyledons being divided into *Choripetalæ*, including all which are either without petals or have them distinct, and *Sympetalæ*, comprising all which, in this country, are comprised under *Corollifloræ*. Thus *Myristicaceæ* and *Lauraceæ* come near *Magnoliaceæ*, and *Euphorbiaceæ* is placed between *Rhamnaceæ* and *Umbelliferæ*, an arrangement which would prove somewhat puzzling to many English readers, but which nevertheless presents some advantages from the point of view of materia medica, as well as from a botanical standpoint. The natural system is not, however, carried out with regard to the animal products; these being few in number are arranged alphabetically.

As an introduction to more extensive treatises on materia medica, this little volume will doubtless be most welcome to students and will serve to give a good foundation in the subject. If the author has devoted space to the history of the drugs which would perhaps have been better devoted to adding matter of more practical use in everyday life, it must be remembered that, the German tendency to prolixity being taken into consideration, the book is a

* This is the Malabar name for the tree. I shall get the botanical name, and let you know by-and-by.—E. B. C.

† Berlin: R. Gaertner. 1884. Crown 8vo. Pp. i.-xxiv. 1-260.

marvel of conciseness and useful information of the kind that the student requires in commencing the study of materia medica.

In the majority of cases the information has been brought up to the latest date, but the notices of substitutions or falsifications of drugs are less full than might have been expected in a work of this kind. Thus we find no notice of Japanese aconite root, nor the means of detecting the various adulterations of saffron and belladonna root and digitalis, nor of the commercial varieties of jaborandi and jalap, ergot and cantharides, etc. Nevertheless, the book contains a large amount of information clearly and concisely put, and will probably give great satisfaction to the class of readers for whom it is intended.

In a few points, perhaps, one may venture to differ from the learned author, and if these are indicated here it is only with a view that the reader may recognize that there is a difference of opinion on these points. *Laminaria Cloustoni* is described (on p. 1) as a peculiar form of *L. digitata*, Lamoroux. On reference to the author's larger works, however, it will be seen that a better way of stating the facts of the case would be to say that it is a distinct species, formerly included erroneously under *L. digitata*, Lam. Dammar resin presents all the characters of a diptcrocarpous product, although it is true that it is usually attributed to coniferous trees. The Arabian aloes possesses different chemical characters from that of Socotra, and can scarcely be the product of *A. Perryi*, as suggested by the author.—*Pharmaceutical Journal*.

THE MACKAY SUGAR CROP.

In accordance with our usual practice (says the *Mercury*), as soon after the close of what may be considered the sugar season—namely, the end of March in each year—we propose to review the returns of last season, and endeavour to lay before our readers such figures as will enable them to form some idea of the prospects for the coming season. We will take a glance, in the first instance, at the result of last year's operations, and it will be found that it is not altogether so unsatisfactory as has been generally supposed. Figures, it is said, may be made to represent almost anything, and though the first impression created by a consideration of last season's returns is by no means unfavourable, yet an intimate knowledge of the district, and a recollection of the general appearance of the crop at this time last year, compels us to remark that the returns, in most instances, were of a most disappointing character. The average production per acre last season was 1 ton, 5 cwt. 0 qr. 14 lb., but it was confidently anticipated that, owing to the large amount of plant cane to be crushed, a return of 30 cwt. to the acre would be obtained. An extremely dry crushing season, however, set in, and although this doubtless enabled the sugar to be made much more expeditiously than usual, yet the canes became so dry and hard that it was not possible, in most instances, to express quite so much of the juice as could have been desired, and the great loss in the quantity of juice was not nearly counterbalanced by its superior richness in density. The area of land under cane for last year's crop was 14,575 acres, of which it was estimated that 13,152 acres would be operated upon. From various causes this estimate was not nearly reached, for only 11,295 acres were cut and brought to the mills. The great discrepancy between the acreage under cane and that actually crushed we are unable to explain satisfactorily; but we assume that in sending in individual returns some of the growers must have overstated the areas under cane. The difference between the first two sets of figures—namely, 1,423 acres—will represent cane which was planted in March 1883, but which would not be crushed until the ensuing season; but how it comes about that the actual area crushed was less by 1,857 acres than was estimated, is difficult of explanation, especially as the area of standovers is very insignificant. However, the 11,295 acres produced 14,240 tons of sugar, and 456,252 gallons of molasses; the number of mills in operation being twenty-five, and of distilleries three. The latter used up 167,959 gallons of molasses, producing therefrom 64,088 gallons o.p., or 83,093 gallons of proof spirit, thus showing a consumption of, within a small fraction, two gallons of molasses to the gallon of proof spirit. The proportion of molasses to the ton of sugar was 32 gallons (a slight excess over that of some previous years). We calculate that the average weight of cane grown per acre was about 20 tons—certainly not more; and this would give a weight of about 16 tons of cane for the ton of sugar produced. We have been shown several returns where sugar appears to have been produced at a cost of 14 and 15 tons of cane to the ton of sugar, and we know of the Colonial Sugar Company, at Homebush, achieving, with the aid of double crushing, very much better results; it being generally stated that the company only used up 10 tons of cane for each ton of sugar. This may be so; but we are satisfied that our average of 20 tons per acre is a fair average one. We cannot pass over these figures, referring to the cost in cane per ton of sugar, without pointing out to all connected with the sugar industry the vastly important question which is involved. Assuming the average was 16 tons of cane per ton of sugar, and that one factory was enabled to produce sugar at a cost of only 10 tons of cane per ton of sugar, we, by the simplest calculation, arrive at the fact that, owing to defective manipulation, a loss of no less than 8,500 tons of sugar has taken place in this district during the last crushing. This is so serious a matter that we think planters would do well to look into it. Lest, however, the casual reader should at once jump to the conclusion that this amount of lost sugar, at £20 per ton would represent £170,000, and that planters by saving that sum would be enabled to pay higher wages, we would point out that, in order to effect the desired saving a very large outlay of capital would be necessitated; and, further, that the cost of manufacturing this last product must be taken into consideration. Still the fact of three-fifths of the sugar grown in the colony (for these figures will apply more or less closely to every sugar producing district) being absolutely lost is a very serious matter indeed; and, since this can only be remedied by the introduction of capital, it forms a strong argument in favour of so shaping our legislation as to secure the confidence of capitalists. For the coming season we find that there is at present an area of 16,963 acres under cane. Of this it is estimated that 15,638 acres will be ready for crushing. Our experience, however, leads to the conclusion that in estimating the probable output so early in the year it would be advisable to make a considerable allowance for contingencies, and we would, therefore, not calculate upon more than 14,000 acres being operated on. The nature of the season during the next six months will have such influence upon the result of the crushing that any estimate made now of a favourable crushing must necessarily be a hazardous one. Comparing the present appearance of the crops, which, though looking well, are extremely backward, with that presented by them generally at this time of the year, we should not anticipate a total output of more than 15,000 tons. With a mild winter and favourable spring we might hope for as much as 17,500 tons; while, on the other hand, if the canes experience the check of a frost and a dry hard spring, it is problematical whether a ton to the acre can be calculated upon. It will be noted that the area under cane this year represents an increase of 2,388 acres over that of last year, and this, we find, is the result of a large increase in the plantings of small growers rather than of the larger ones. We can only, in conclusion, express the hope that a favourable season may be experienced, and that, from some source (the direction of which we confess our inability to indicate), sufficient reliable labour may be forthcoming to harvest the crop.—*Queenslander*.

OLIVE-OIL MAKING IN SOUTH AUSTRALIA.

BY DRUNI.

Among the many new industries so successfully undertaken by the enterprising colonists of South Australia, there is not one that promises to take a higher place in the future prosperity of the country than the cultivation of the olive. There is probably no country in the world in which the soil and climate are better suited to the growth of the tree, for no matter where it is planted it flourishes most luxuriantly, and without the least attempt at cultivation it produces a good crop of fruit. Everywhere I went in the interior of the colony I found the olive grow

ing, and whether planted in a close group as a breakwind or as a hedge, the trees were always healthy and often covered with a heavy crop of dark-purple berries. But though so generally grown they have not been hitherto regarded as of much economic value, and it may fairly be estimated that oil to the value of many thousands of pounds has been allowed to run to waste for several years past. At present efforts are being made to utilise this valuable product, and there are already several purchasers of ripe olives in the city of Adelaide, though the rate of wages renders the task of gathering the fruit not a very profitable one. Among the earliest to perceive the value of the olive as an agricultural product was Mr. Samuel Davenport (a gentleman, whose eminent services to the country of his adoption have lately received the well-merited reward of knighthood), who commenced planting olives somewhere about twenty years ago. Hearing that Mr. Davenport could show me the whole process of growing, picking the fruit, crushing and pressing the oil, I gladly accepted an invitation to visit him at his residence, near Burnside, one of the hillside suburbs of Adelaide. The morning was delightfully fine, and the gardens and fields we passed by looked bright and fresh after the ample supply of rain that had fallen the previous fortnight. On the way I passed a very extensive orangery in which the trees had not yet come into bearing. The soil was well cultivated, and the trees were thriving very vigorously. Careful preparations had been made to preserve the fruit from marauders, for the ground was enclosed with a high stone wall, having a formidable array of broken bottles on the top.

Beaumont, the residence of Mr. S. Davenport, is a small property of about fifty acres extent. The soil is of a rich dark-brown colour, of greater strength than the chocolate loamy soil I had seen so much of in my journeys to the northward. Only a small portion of the land is occupied by olive trees, and they are so scattered about in clumps and lines that I could not arrive at a definite idea of the area occupied by them. Since he first commenced olive cultivation, Mr. Davenport has seized every opportunity of securing any new variety of the tree that came in his way, and the result is that he has a greater variety of olive trees growing on his property than is to be found on any one estate throughout Australia. The Bouquetier and Verdale appear to grow better and give heavier yields of fruit than any other varieties. The small olive, called the bird's eye, is a heavy bearer, and the oil yielded by it is of excellent quality. Many of the large-fruited varieties of Spanish and Portugese olives grow well, and give good crops. Which is the best variety of olive to grow in South Australia has not yet been determined, nor are the growers decided as to the best mode of pruning the trees. In very many instances, I believe, the olive-growers avoid the danger of wroogly pruning by not pruning at all. Establishing an olive-yard would appear to be a very simple operation, for the trees grow as readily as a plantation of young gum trees. The greatest difficulty in the way of establishing the industry is the gathering of the fruit, which is a troublesome and costly operation. There being no trained labourers to do the work, the proprietor of an olive-yard is obliged to depend upon boys, who idle away their time directly they are left to themselves, and both men and boys are apt to injure the trees in picking by destroying the fruit-bearing spurs and thus lessening the next year's crop. With the few varieties of olives that separate readily from their stalk the crop may be gathered by shaking the olives on to cloths spread under the tree, or they may be beaten off with light cane sticks, but unless practised by careful and skilful hands, the latter mode of harvesting the fruit is apt to do much damage to the fruit spurs.

The plan of gathering the crop at Beaumont is to employ two or three careful men with a few boys as assistants. The former gather the fruit within reach, while the latter, mounted on ladder steps, collect that on the higher branches. With quick eyes and nimble hands one can gather from 1 cwt. to 2 cwt. of olives per day, which is paid for at the rate of from 3s. to 4s. per cwt. The olives as they are gathered are put into boxes and carted to the oil mill, which is placed in an open building adjoining the winepress. Here the olives are freed from leaves and twigs and placed in the mill. This is in the form of a Chilian mill, the circular receptacle being formed of one block of granite, in which revolve two broad granite wheels, each weighing seven tons. These wheels are worked by a horse-power, in the same way as a pudding-mill is worked. Under these heavy rollers the olives are soon crushed to a pulp, the seeds being ground to powder. About 1 cwt. of olives are put into the mill at a time, and in a quarter of an hour they are sufficiently macerated for the next process. This consists in putting the purple-coloured pulp into bags made of a material similar to that used for making woolpacks. These bags are strongly but loosely made, so as to facilitate the escape of any liquid when under the press. When about a dozen of these bags are filled they are placed one above another in a press of rather peculiar construction. The bags are enclosed in a strong iron-bound frame, resting on a cemented bottom with a false bottom grooved, so as to allow any liquid to run away. Pressure is applied by a piece of wood called a tongue, which is attached to a heavy beam or lever, weighing about two tons. This tongue is jointed at its junction with the lever, so as to preserve a perpendicular pressure as the lever descends. It appears that the kind of pressure obtained by this lever has been found by experience best suited to extract the oil. The strong power of a screw-press would, it is said, confine the oil in the pulp, while the slow, steady pressure of the lever causes it to trickle through the bags. As the oil exudes it runs along channels formed in cement to large slate receivers, which are filled to within 18 in. of the top with pure water. The delivery pipe is about a foot below the surface of the water, so that the fleshy portion of the fruit remains in the water while the oil rises to the top and is taken off with small tin skimmers, something like cream-skimmers unperforated It is then in what is called the honey state, and is placed in large tin receivers from which the light is carefully excluded. Here it deposits stearine, and is then removed to other tin receivers, where it fines itself, and after being passed through filters is ready for delivery. This oil of the first pressure is called virgin oil. The pulp is then taken from the press and thrown into a heap, hot water being mixed with it. It is then again bagged, and placed under a press reserved for this purpose, in which none of the first quality of oil is ever pressed. The oil of the second pressure is of an inferior quality, and is run into a cistern kept for this quality of oil. It is used by manufacturers, and is sold at a price considerably below that of the virgin oil. The most critical cleanliness is practised in making the oil, the mill and presses being washed every evening with hot water and soda. About 500 gallons of olive oil are made per annum, which is sold at 10s. per gallon. The oil made at Beaumont has received the highest commendations from some of the best judges in the colonies and in Europe. Some time ago Mr. Davenport sent a sample of his oil to experts in Italy, and the report he received on it was very gratifying. It has a fine flavour, and resembles the "Sublime" oil more than the olive oil of commerce. Most of those who taste it unhesitatingly pronounce it to be superior to the Lucca oil one gets in the grocers' shops.

That olive oil of the finest description can be grown in the neighbourhood of Adelaide does not now admit of a doubt. There remains, then, the question of the yield per acre to solve before one can have a clear idea of the paying character of the enterprise. But though olive-growing was commenced several years ago, it is very difficult to give an estimate of the return that may be fairly expected from an acre of olive trees in full bearing. The original trees were generally planted in small groups or in lines along a boundary fence, and never in large numbers. Even the oldest trees in the colony, with such a long-lived plant as the olive, can scarcely be said to have yet come into full bearing. When a group of olives was planted the trees were invariably placed too close together. Mr. Davenport is of opinion that they should be planted 30 ft. apart, which would give 48 trees to the acre. The olive, like many other fruit trees, bears heavier crops on alternate years. At Beaumont there are some trees that will on alternate years give 1 cwt. of fruit, the produce of which may be given at 1¾ gal. of oil, which, at 10s. per gallon would make the maximum yield a little over £41 per acre. With well-matured trees and a proper system of pruning there is no doubt that excellent returns can

be obtained by growing olives, even though an average of £41 per acre may never be realised. Once planted, the olive trees require very little attention beyond ploughing the ground so as to leave it open to absorb any rain that may fall, and exercising care in gathering the fruit. The question of pruning the trees is one that is of great interest to olive-growers. From what I have learned, the plan usually adopted with ordinary fruit trees will answer very well. Mr. Hardy, of Bankside Vineyard, noticed, during a tour he made lately through Portugal and Spain, that the olive trees in those countries were kept very low, probably to facilitate fruit-gathering, as well as to prevent the wind getting a hold of them, and they were opened out in the middle. The young olive trees at Beaumont have been attacked during the last few years by small beetles, which injure the trees by eating the young leaves. Several attempts have been made to destroy these insects, but the only effectual remedy for the evil is to keep tame seagulls in the plantation. So far as I could learn, Beaumont is the only place at which this pest has made its appearance. Some extensive olive plantations have been made during the last five or six years, one of which is fully 150 acres in extent. When this plantation is in full bearing—and it has already commenced to yield fruit—the industry will be thoroughly tested.

A large portion of the Beaumont property is under vines, the wine from which has achieved a fair reputation. The cellar is the most complete building of the sort I have seen. Every arrangement for the convenient treatment of the wine has been carefully studied. The walls are of stone, and very thick, and the ceiling is packed with sea-weed to keep out the heat of the sun. The floors are well made, and the comfort of the men working in the cellar when the must is fermenting has been well looked after. The wine made at Beaumont is of a rich generous character, the finest perhaps being that made from the Madeira grape, which bears a strong resemblance in character to the European wine known by that name.—*Australasian.*

THE TENGKAWANG.

BY H. P. BAKKER OF SANGGAU.

As of late years the Tengkawang attracts more and more attention, I have deemed it expedient to collect what I know about the growth, the crop, the preparing and export of the Tengkawang fruits in the present article, and though it makes no pretentions to scientific value,* yet I flatter myself that the contents will be found interesting enough to deserve the attention of the public.

Formerly only the tallow of the Tengkawang used to be exported from the west coast of Borneo, but since 1878 a change has taken place in this, and the dried pulp of the fruit also is shipped to Singapore.

The Tengkawang grease, or vegetable tallow, called by the Natives *minjak tengkawang*, is the produce of the fruit of a tree, of which there are half a dozen varieties; four of these are designated as *tengkawang*, also *engkawang* and *engkabang*, while the other two are reckoned by some as belonging to the same class, by others not. The first four, called in this article the Tengkawang proper, are:—

the *T. toengkoel.*
the *T. rambei.*
the *T. lajar* and
the *T. goentjang.*

The two other sorts are:—

the *madjan* and
the *terindak.*

The grease, prepared from the fruit of the latter trees, bears like that of the other sorts, the name of *minjak tengkawang.*

All the varieties of the Tengkawang proper are found growing wild in the whole of the Residence *Westerafdeeling Borneo*, with the exception of the regions lying along the River Kapoeas beyond Silat, while the *madjan* and *terindak* seems to occur every where in those parts. The region where hitherto the most Tengkawang is collected, is *controle-afdeeling* Sanggau and Sekadau, and the Indian appellations, given them in this article, are those which are in general use there.*

Let us first examine the Tengkawangs proper.

The trees, with the exception of the *T. goentjang* prefer the banks of rivers and rivulets, especially the *tandjongs* or land-tongues, formed by the bends of the latter, where the loam is mixed with sand, and the soil is moreover more humid than on other spots. But they also appear on heavy clayey soils and on the mountains, though they thrive there less luxuriously and yield fewer fruit. Though they can bear up against inundations of short duration, and seem even to thrive the better for them, yet an inundation of long standing is fatal to them. This was the case after the flood of the Kapoeas in August and September 1878, when thousands of tengkawang trees perished, which entailed great loss to the population.

The *T. goentjang* is distinguished from the other three species, first by its thriving best in soils which, situated on the upper courses of creeks, are occasionally submerged in consequence of insufficient drainage; and secondly by the trees not growing higher than 6 à 7 metres, and the stem not thicker than 0·15 à 0·20 M. For the rest its outward appearance is like the other sorts, but its fruit are rather larger than those of the *t. rambei.*

The trees of the *t. toengkoel*, *t. rambei* and *t. lajar* are very much alike outwardly. They consist of heavy trunks that branch off not very high above the ground and bear only a few main boughs, which, when the tree has the necessary space (which is but seldom the case) are thick, long and almost horizontal. With their manifold side branches and large leaves these main arms form a heavy, thick tuft.

At the base the trunk is not round, but throws out several shoots (banirs). The roots are thick and run out far along, and even partly over, the ground.

The biggest are the trees of the *t. toengkoel*; but specimens of the *t. rambei* and *t. lajar* with a trunk one metre in diameter are not rare.

The wood of these trees is light and soft, and is classed here among the inferior sorts. Exposed to air and damp it soon rots. The trunks are used for floaters under floating-houses, and they are also sawn into planks, which are very fit for wainscottings indoors.

The fruit of the *t. toengkoel* are in their cross-section almost perfectly round, lengthwise oval, and rather pointy at top. Those of the other three sorts are of the same shape but rather more tapering. The pulp is of a yellow colour; on germinating or drying it mostly splits into four.

This pulp is enclosed in a hard ligneous shell with a smooth surface. At the foot the fruit bears five thick ligneous leaves, which are pretty firmly joined to the shell; a part of it runs out into membraneous appendages which surround the shell, but are loose. These appendages the Natives call *sajap* (wings). They are in the *t. toengkoel* a little longer than the fruit, in the *t. rambei* and *t. goentjang* still longer, and in the *t. lajar* they attain even a length of 0·15 M. In this variety they form a kind of chalice, in which the fruit is completely concealed, and are moreover tough and hard.

The fruit of the tengkawang proper grow in bunches, as also the *rambei*. Those of the *t. rambei* are about of the same size as the forementioned fruit, thence the name of the tree. The fruit of the *t. lajar* have about the same dimensions, but those of the *t. goentjang* are

* A scientific treatise of the Tengkawang was produced by Professor W. H. du Vriese, in 1861, entitled: "Minjak Tengkawang," also Bishop Grevelink's "Planten van Nederlandsch Indië," 1883, p. 456 199 and "Minjak Tengkawang and Minjak Tangkallah." Ind. Gids, 1881, I. p. 350.

* In the well-known work of de Sturler "*Handboek voor den Landbouw in Ned. Oost-Indië*," p. 686 s.q.q., several sorts of tengkawang are quoted, that are unknown here, such as *T. blongsong*, *t. vimit*, *t. batoe* and *t. rabe*; but probably these are only other local appellations for the sorts mentioned here. The *t. penang*, also mentioned, is indeed found here, but its fruit are not collected, because their proportion of fat is too insignificant to be worked with profit. It appears by the work quoted that the *terindak* belongs to the genus Hopea, and I believe that the *madjan* too ought to be included. Nevertheless, I have thought it proper, for the sake of a convenient view, to call the *t. toengkoel*, *t. rambei*, *t. lajar* and *t. goentjang*, the tengkawang proper, in contra-distinction to the *madjan* and *terindak.*

rather larger; the largest fruit, however, is produced by the *t. toengkoel*, of which I have seen some of the size of a duck's egg. Why this sort is so called, is not very clear.

The *t. tajar* owes its name to the fact of its fruit's falling straight downwards, but by the resistance of its outward bent wings float hither and thither before reaching the ground, which the natives call *belajar* (sailing).

The fourth sort is called *t. goentjang*, because the fruit is made to fall by shaking (*t. goentjang*). As it is much less frequent than the three other sorts, and every tree produces, besides only a couple of catties of dried fruit, we will leave it without further notice. To obtain the tallow the fruit is treated in the same manner as that of the *t. toengkoel*.

For a good produce it is necessary for the dry monsoon to last long, with a little rain it is true, but without heavy showers. Moreover the transition must be gradual, and the wet monsoon not bring too much rain; for heavy showers in the transition season cause the blossoms to fall off before the fruit are formed, and even the young fruit are also subject to fall if the rainy-monsoon is too tempestuous. As now, in these parts, especially in the dry monsoon and in the transition season, rains are mostly preceded or attended by high winds, it is a matter of course that the tengkawang proper but seldom gives fruit.

Frequently the trees will blossom luxuriantly, without yielding any crop.

This is the case with all the four sorts of the tengkawang proper. If one kind bears, the others will bear too, and otherwise none of them will produce anything.

It is calculated that the tengkawang proper bears fruit once every five years. Sometimes, however, a period of eight years will intervene between one crop and the next, and in general, perhaps, a good crop will occur only once in thirty years. Though much fruit was gathered in 1878 and also this year, yet the produce in those years is reckoned to have been below mediocrity. This year, according to a fair estimate, only a fifth part of the trees bore fruit, and that not even abundantly.

As has been said above, the tengkawangs proper are all found growing wild. The *t. toengkoel*, *t. rampei* and *t. lajar* grow in some places by hundreds and thousands together along the *Soengeis* (smaller rivers), and this is not surprising, when we consider that the fruit, falling to the ground, germinate in a few days, or floating on the water are carried down by the current and are arrested lower down on several projecting spots.

Such woods are nobody's private property. Any one may gather as much fruit as he likes; only the self ruling Radjas have from old the right to keep the population from some of these woods and have the fruit reaped for their own use.

Of the different tengkawangs the *t. toengkoel* is the only one that is cultivated. Such plantings, like those of other fruit-trees, are called *tembawangs*. This word cand hardly be rendered by *gardens* or *orchards*, for the trees are planted without any regularity, and scarcely anything is done for their culture.

Formerly many plantations of tengkawang were met with along the banks of the Kapoeas; but the inundations of 1878 have destroyed them all, except those planted on hilly grounds.

Opposed to these plantings of *tembawangs*, stand the *kampongs*, that is groups of trees of one and the same kind growing wild. In the same way the well-known iron-wood (*teblian*) grows in kampongs.

He who plants a *tembawang*, remains the owner thereof. He may transfer his rights to others, and these rights, on decease, pass to the heirs, but very rarely are the *tembawangs* divided after the death of the proprietor. They mostly remain the joint property of the heirs.

The planting of the *t. toengkoel* takes place in the following manner:—A piece of bamboo 0·2 M. à 0·3 M. in length is filled with earth and the fruit put upon this, very soon it begins to shoot, and in 3 or 4 months the stem has already attained a height of about half a metre and given birth to three or four leaves. Then the remains of the fruitpulp are removed, and the bamboo with the plant in it is planted in the ground. This is generally done in fields that have served for growing paddi, some months after the harvest of this plant; for the wild wood is then not yet grown up high, and therefore need not yet be cut down.

The fruit of the tengkawang soon germinate. If they remain lying on moist ground, the first shoots of the root apper within 10 or 14 days; the hard shell is then of course already burst open and disengaged along with the other appendages from the pulp.

The planting is rarely performed regularly, and always too close together. Sometimes the intervals between the young plants are only one or two fathoms. The Native says that he plants them so close together because a part of them always die, and he intends afterwards to cut down the less vigorous plants.

The plants now set in the open ground are mostly abandoned entirely to their fate, and grow up along with the wild wood. This acts prejudicially to their development, but fortunately they grow up pretty quickly, and thus partly remain alive. During the first years the wild wood is seldom or never cut down, and mostly the planter does not look after his property till the advent of a tengkawang year, so commonly fully four years after the planting. He then cuts away the wild wood, so that, it is true, the tengkawang trees now come to stand rather freer, but yet much too crowded. It would indeed be desirable to clear away also the poorer trees; but as these have already attained a certain size, he finds it a pity, and leaves them there; so then the trees are in each others's way, shoot up thin and bear fewer fruit.

It would appear that earlier generations used indeed to thin their plantations. At least in old *tembawangs* the trees often stand at a proper distance from each other.

For the rest, nothing more is done to the tembawang till the trees have blossomed and the fruit appear. Then all the wild wood is lopped away with the object of facilitating the gathering of the fruit, admitting a freer access of wind and air, and preventing monkeys and other animals from reaching the trees by means of the wild wood.

In a wild state, of course, the trees grow much more irregularly even than in the plantings.

About the growth of the tengkawang and the age at which they begin to bear fruit, it is difficult to give any reliable statements. Both depend so much on the nature of the soil, and as regards the *tengkawang toengkoel*, also on the way of planting. Some of the stems of the latter species have at five years of age a diameter of 0·15 M., and some there are which at 40 years of age first attain the size of 0·60 in diameter.

Some plants commence bearing a few odd fruits in their eighth year, but as a rule it seems that this does not occur till the twelfth or thirteenth year.

It is also difficult to infer how much fruit a tree can produce. As to the *tengkawang*, this is even impossible, as in a wild state the young and old trees grow promiscuously. Of the planted *t. toengkoel*, however, it is generally said that old trees, that are planted in good soil and can grow out freely, produce, in good years, so much fruit as will yield 100 gantangs* of *paddi tengkawang*. The meaning of this term will appear later.

One with another, however, it has been reckoned that the fruit of good trees yield from 20 to 40 gantangs of *paddi tengkawang*, and a crop of 100 gantangs is therefore no rarity.

As the price of the paddi tengkawang has varied this year from 8 to 11 dollars, it may be assumed that the produce of one tree, worked to the article aforesaid, is worth from $1·5 to $4. in exceptionally favourable cases even $11.†

Let us now proceed to describe the manner in which the fruit of the tengkawang are gathered in and worked. As we have seen, the planting and maintenance of the tengkawang plantations cost the Native very little labour. Nor does the heavy work begin till the fruit are ripe.

As soon as it appears that the tengkawang bears fruit, the Malay population bestir themselves, forsaking their habitual indolence. You hear then of nothing but the tengkawang, which is very natural, as it yields the population so much profit. Malayans and Dajaks, who have temba-

* The *gantang* is a measure of various capacity in various parts. At Sanggau it is equal to about 3¼ Litre. In measuring *paddi tengkawang* the *gantang* is not swept off clean to the brim, but is left with a head, as is done in Holland in measuring potatoes.

† The dollar values now at Sanggau *f*2·25.

wangs, cut them open and build therein cabins, while such as wish to collect forest tengkawang, devote themselves with all their might exclusively to that purpose. As soon, now, as the fruit is so ripe that they are likely to drop, men, women and children leave their homes and settle in these said cabins, the consequence of which is that the Malay kampongs are often abandoned by three-fourths of the population.

The fruit are not plucked off, they are allowed to drop. The Native here says that the plucked fruit yield less tallow.

If now at such a time the weather is tempestuous, it is a great advantage to the population, for then the fruit fall in vast numbers, and the gathering is soon accomplished; otherwise it may last six weeks or two months. A beginning is made very early in the morning to collect the fruits; these are picked up from the ground and cast into a basket carried on the back, and afterwards carried home, the whole day long. That this work is begun so early as at peep of day is to prevent the fallen fruit of the foregoing night from being stolen, and moreover because the wild hogs are exceedingly fond of them. In the woods, where a number of trees are crowded together, there is less danger of these animals, but in the more retired tembawangs they are a very plague.

When the fruit are brought home, they are beaten with a stick so long, till the appendages mentioned above are removed, and then they are thrown into heaps till the gathering is done. It is advisable to protect the fruit against rain, as otherwise some of them will soon shoot, which must act prejudicially both on the quality and quantity of the tallow.

The ingathering of the *t. lajar* is generally performed in a rather different way. The wings of the fruit are bitten off as they are picked up, which is no easy matter, as they are very tough. For this reason the fruit are sometimes left simply a few days on the ground, till they begin to germinate, and the wings with the hard shell loosen of themselves. When the gathering is accomplished, the greater part of the gatherers return home.

Then large baskets are made of split bamboo, which can contain from 4 to 500 gantangs. The fruit are put in these, and thus suspended in the water on rafts, whereby it is a necessity that the baskets be not full, lest the fruit that swells enormously by being steeped in water, should burst them. Care must also be taken that they remain quite under water, to prevent the fruit from rising to the surface and germinating.

This steeping of the fruit in water has the following consequences:—First, the shell becomes softer and bursts of itself by the swelling of the pulp. Secondly, the tengkawang, that has remained long enough in the water, is less exposed to the attacks of the *boeboek* (worm); and thirdly, it is pretended that the quantity of tallow increases considerably by the action of the water upon it, and is more easily extracted from the fruit. Whether the proportion of tallow actually increases is a thing that I will not determine; it is, however, a fact that the longer the fruit remain in the water, the more tallow can afterwards be obtained from them; but this may also be explained by the common union of the parts of the pulp being broken by the action of the water, and the separation of the tallow thus becomes easier.

It is better to leave the fruit for 30 or 40 days in the baskets, but sometimes they are there as long as three months. A shorter period than 30 days, however, is not advisable, because then the paddi tengkawang is liable to be infested by the boeboek, and yields less tallow. Whereas if the fruit is left longer in the water, it does result in a more copious yield of tallow, but at the expense of the quality and the peculiar yellow colour which distinguishes the superior tengkawang tallow. It is also specially lighter.

After the fruits have lain long enough in the water, they are taken out and peeled by hand, or else the shells are beaten off with a piece of wood; the pulp then mostly splits into four and is much swollen. The next process is the drying, on frames knocked up in the interim, and not covered, on which the fruit are spread out. On the appearance of rain, they are covered up, and every evening they are brought in-doors to expose them again in the morning till they are quite dry. Then they are called *paddi tengkawang*, which term implies the dried, split pulp. If the *paddi tengkawang* is not stored up quite dry, it will soon rot; but if the process is carefully attended to, it can keep a whole year.

The above treatment of the tengkawang fruit, which might be called the wet treatment, is in general use in the Kapoeas territory. A very different treatment is adopted in other parts, for instance, in Landak. The treatment in use there may be called the dry process. The fruit are not at all steeped in water, but are dried, even over a fire. The paddi tengkawang obtained in this manner, is according to the general opinion of the Natives here, of much less value than what is obtained by the wet process. It is soon attacked by *boeboek* and yields also less tallow; but then again the tallow is much harder.

Here at Sanggau the tengkawan fruit are treated in another manner. Directly after the gathering, the shell is broken, the pulp is cut into slices and these are dried in the sun, to obtain from the product thus treated, which must then be immediately pressed, the so-called *minjak tengkawang Soentie*. This is considered the finest of the tengkawang tallows, and is only made in small quantities for private use, viz., for culinary purposes. The quantity of tallow obtained in this manner is, in proportion, much less than when the tengkawang is treated according to the wet system. Hence it is seldom applied.

Let us now examine in what manner the Native separates the tallow from the paddi tengkawang.

He begins by pounding the paddi. This is often done in the common rice-block with the rice-pestle; but sometimes the pestle is made of a short heavy piece of wood, fixed to a long pole, placed horizontally, and turning in the middle round a horizontal axis; then they tread upon one end, which raises the stamper, and upon being let loose the stamper falls into the block.

When the pounding is done, the tallow is to be expressed. For this two arrangements are required, one to seethe the meal and one to press it. This seething and pressing is done simultaneously.

For the seething a long hollow wooden cylinder is used, in which a loose bottom of split bamboo at a little distance from the base is placed, and then closed at top with a wooden cover. This is suspended with its base over the water of a large iron pan, in such a manner that the bottom does not reach the water. It is then filled with tengkawang meal and closed, after which the water is made to boil. The steam then mounts into the cylinder and penetrates to the meal, which becomes more compact and sinks; then the cylinder is filled up again with meal, and when all the meal is thoroughly heated to the top, it is ready to be pressed. To render the spreading of the steam as regular as possible, a piece of bamboo is fixed in the middle of the cylinder vertically over a hole in the bottom, the sides of which are perforated here and there.

The size of the cylinders is various. Some hold as much as 75 kattis of meal.

The press is more than a fathom high, and consists of two horizontal beams, one of which rests on the ground, and connected to each other with supports. In the upper beam is an oblong square vertical aperture or groove, in the lower one a square hole. Between these two beams are two heavy pieces of wood, placed with their broad flat sides towards each other. They are hewn thin at the extremities, and rest with one extremity in the hole of the lower beam, while the other extremities are enclosed in the above-mentioned groove, in which they can be moved towards and from each other. At the inner side of each is a notch running slanting downwards, in such a manner that if the pieces of wood are brought together with their flat sides against each other, the notches tally. If, now, you proceed to press, the two pieces must be placed so as to form a V; in the notches an *oepeh* (sheath of the pinang) is bound, forming a slanting gutter protruding out of the press; then a bag filled with hot tengkawang meal is laid between the press above the pinang sheath, and then the two pieces of wood are driven together by means of quoins which are driven into the mentioned groove. The fluid grease then flows from the bag into the pinang-sheath and so out of the press, and is caught up in limbs of bamboo, or in a sort of tubs made of bark. The press-bags must be made of plaited ratan, otherwise they are like to burst. The driving of the quoins is hard work, and the two men who do this place themselves for that purpose upon the upper beam.

If the tallow is intended for culinary purposes it must be strained.

After the first pressing, the rattan-bag is taken out of the press, the meal that is in it, well shaken, and replaced with the topside under. After a second pressing all the fat is far from being expressed, and therefore the pressed meal is sifted, the finer part thrown aside and the coarser is again pounded, seethed and pressed. Three or four persons can seethe and press about 3 piculs of meal in one day.

It is evident that after this operation there must still remain some fat in the refuse, that is thrown away here, and that one working with better appliances will get from the same quantity of paddi more fat than the Native.

The paddi tengkawang differs considerably in weight and proportion of fat. The heaviest and richest is that produced from sound fruit that have not germinated, and have lain 30 à 40 days in the water. Such paddi tengkawang weighs 3 piculs per 100 gantangs, and yields 120 katties of tallow. The tallow of the tengkawang fruits that were either not sound, or partially germinated, or have not been steeped long enough, is lighter, so that the weight of 100 gantangs of the paddi varies from 230 to 300 kattis, but amounts on an average to 270 à 280 kattis. From this inferior minjak is also obtained.

The proportion of tallow in the four sorts of tengkawang proper is about equal, provided the fruit be properly treated. Now, however, we have seen that the fruit of the t. lajar often lie on the ground till they germinate, which has an injurious effect on the quantity of fat. This paddi is mostly mixed with that of the *t. rambei*, and an equal weight of this mixture yields less tallow than the same weight of good paddi of the *t. toengkoel*.

We have now considered how the paddi and minjak tengkawang are prepared, and we shall have something to say further on about their importance in commerce. For the present we will return to the *madjau* and *meridak* mentioned above.

These trees grow wild, by preference along the banks of smaller rivers in marshy ground, but are also found occassionally further up from the banks. People do not plant them.

They are big trees like the tengkawangs proper, but their wood is more durable, and they do not perish from inundations. The *madjau*-wood is made into *sampans* (a sort of craft) and planks, while the *terindak* wood, which is heavier than water and much resembles the favourite *tekem*-wood, is applied to manifold purposes. It is hard and proof against damp.

The fruits are of almost the same shape as those of the tengkawangs proper, but are much smaller; those of the *madjau* are about an inch thick, those of the *terindak* are of the size of a coffee berry.

Both these trees do not, indeed, bear every year, but yet more frequently than the tengkawangs proper. In the years when these produce fruit, little trouble is taken to gather them. As the trees generally hang over the water, a part of the fruit fall into it and float away till they are stopped by some obstacle or other; here they collect into a heap and are scooped up by the Natives. The fruits of the two sorts are thus commonly mixed up together.

The fruit that fall on the ground are allowed to remain there in the tengkawang years, but when the tengkawang proper does not bear they are collected. The underwood is first cut away and all the leaves removed to as to leave the ground quite clean. As the fruit are too small to pick them up one by one, they are not gathered every day, but only when a sufficient quantity has fallen to sweep them together. Thus the fruit have often partly germinated, which is injurious to the produce.

The fruit are then also steeped in water, either for a longer or shorter time according as they have germinated or not. The wet fruit being first dried, the shells with their appendages are loosened by stirring and pinching them well in a *bakoel* (a kind of basket) with the hand, and then removed by sifting or winnowing.

The paddi of these sorts is treated in the same manner as the tengkawang proper to get the tallow from it.

The proportion of tallow in the paddi of *madjau* and *terindak* is much smaller than that of the paddi of the tengkawang proper, and may be compnted at about one-sixth of its weight only.

If the *madjau* and *terindak* are worked separately, and the fruit be not allowed to germinate, the tallow obtained is of a very good quality, but always softer and of less value than that of the tengkawangs proper. *Madjau* tallow is of a lighter colour, *terindak* tallow greener.

Of old the tengkawang tallow was used by the Natives for lighting, further mixed with resin, for calking vessels, and lastly as a condiment with rice, or for preparing condiments. The fat required for this last purpose every one used to make for himself as much as possible, and employed the best fruit, which were carefully treated. The fat of the *madjau* and *terindak* is not fit to eat.

As the demand for the tallow increased, people began to adulterate what was intended for exportation.

It is a lamentable fact that traders of these countries are so apt to bring adulterated and sophisticated productions to the market. Nor has tengkawang tallow escaped their inventiveness in this way; powdered earth-fruit and water was mixed up with it. The tallow when still fluid can bear one-third of its volume of water being mixed with it, without its being easily perceptible when solidified, unless in burning, for then it will splutter. The delicate yellow colour is indeed lost by such a commixture, but this can be restored more or less by several artificial means.

The tallow that was exported used to be made either entirely of the paddi of t. *toengkoel*, that is kept and worked separately, or else of a mixture of different tallows from the t. *lajar* and t. *rambei*, and sometimes also of *madjau* and *terindak*. An examination into the physical and chemical properties of the tallows could, therefore, never lead to definite results. To be able to do this properly, it would be necessary to buy up a certain quantity of each sort at the time of the gathering and to work these separately.

Upon to the year 1878 it remained a regular thing to export the tallow. It was bought up here for $6 à $7 per picul, whereas the price of the paddi tengkawang amounted to $4 à $7 per 100 gatangs.

In the said year, however, a complete revolution took place in the tengkawang trade. Sundry Chinese began then to buy up the paddi tengkawang, and thence the price of this article rose to $10 the 100 gantangs, or about $3·50 per picul; however, the greatest quantity was bought up for less, and disposed of with great profit by the purchaser at Singapore. This fact soon became known, and the price of the paddi tengkawang of such a nature, that the preparation of the tallow for private use could no longer yield any profit, and every one therefore was eager to sell it.

Add to this that the Native began to feel the want of the tallow less. Petroleum as a lighting oil had already superceded it in a great measure; also cocos, cocos-oil and other ingredients for culinary purposes had become of easier acquisition than formerly, and had partly rendered the use of tengkawang tallow for that purpose superfluous. So the want of this tallow for the native household was very much diminished, and this was an additional reason for the Native to be eager to sell his tengkawang.

In 1878, I believe, only paddi tengkawang was exported from the Kapoeas territory which was duly prepared after the wet system. The converting of this to tallow and other matters by European industry must therefore have yielded good results.

Not till this year did the trees bear again.

Allured by the profits obtained by some in 1878, a fierce contention took place among the different Chinese and Malay traders, as to who should first buy up the greatest quantity of paddi tengkawang; and the consequence was that the price rose to $4 per picul.

The price of paddi *madjau* and paddi *terindak*, however, was, as formerly, lower than that of the tengkawang proper. This paddi is also less exported.

The natives seeing that the purchasers attend less to the quality, and hearing that the paddi after the dry system produced as much in the Landak, began to slight the process. Some allowed the fruits to remain but a very short time in the water, say 8 or 10 days, and dried them at once; such paddi must therefore be sooner infested by the *boeboek*. Several sorts were mixed up together and even with paddi of *madjau* and *terindak*, even the paddi that was far from being sufficiently dried was bought, and put into *goeme*-bags—the ordinary way of packing; no wonder that the product arrived half rotten at Singapore. Nor could the Malayan resist the temptation to adulterate, and he mixed his paddi here and there with worthless wild fruits.

The delivered quantities were so great that at Pontianak the available ship's storage was insufficient to convey them to Singapore.

In July the price suddenly fell, and a picul of paddi could not fetch here more than $2·35; by degrees, however, it has risen again to $3. The cause of this sudden fall is, according to the Chinese dealers, owing to the product being disappointing, attacked by boekoek, partly rotten, and on being worked less rich in tallow than had been expected. This result cannot surprise us, considering what has been said above, and was actually foreseen by some, for which reason the intelligence of the sudden fall in price could be accepted as true.

That the paddi tengkawang prepared after the wet process is better than the other, seems also to be already known to the trade. At least the Chinese traders say that at Singapore the former is worth $20 per koyang of 40 piculs more than the latter.

Whether the long continued action of the water does really increase the proportion of tallow, is a point that well deserves further investigation. But be this as it may, the first mentioned sort has this advantage, that it is only after a considerable time that it is attacked by the boebock, a circumstance of great importance in sending the product over sea.

The traders have suffered pretty considerable losses this year. Only a few have any knowledge about tengkawang; they will have to be more careful in future in their purchases. It is rather difficult, but for people well acquainted with the article, it is not at all impossible to distinguish the duly prepared paddi tengkawang from the inferior sorts.

If the advantage of the wet process be acknowledged, it would besides be worth consideration, where the natives follow the dry system, to point it out to them, and persuade them to abandon that method.

The profits which the tengkawang yields to the native population are so great, that it is well worth while to encourage further planting and a proper working of the product. The first, indeed, is not necessary in the Afdeeling Sanggau and Sekadau, for the population there do plant of their own accord; but, as has already appeared, their *way* of planting and their maintenance of the plantations, leave room for improvement. On the other hand, now the people have once departed from the good old way of working, it will perhaps cost some trouble to get them to return to it again.

To judge of the profits derived from the tengkawang by the population, we give the following figures. From the *Afdeeling* Sanggau and Sekadau a quantity of more than 23,000 piculs of paddi tengkawang has been already exported, for the purchase of which, according to a fair calculation, a sum of $75,000 was required. Besides this some traders have a large store, and the population have also used a part for preparing tallow, so that the crop of this year in these parts may be safely stated as representing a value of more or less $100,000.*

The tengkawang crop is, then, for many Natives an ample source of revenue, and is becoming of more and more importance for them, as getahs and ratans are becoming scarcer.

Before concluding this article, I wish for the sake of completeness, to add a few words about a couple of other fruits occurring here, that also contain fat, namely:—

The *belaban* or *melaban*
The *kelakki* and
The *tengkalak* or *malih*

The *belaban* and *kelakki* trees grown in marshy ground, especially along the banks of smaller rivers. They are rather big, and the belaban wood especially may be reckoned among the good sorts. This wood makes the best short oars, the kelakki long oars.

The fruit of the kelakki have the size of a nutmeg; the outer shell loosens of itself and discovers then 1, 2 or 3 small fruit, enveloped in two more skins. The outer of these skins, when dried, is loosened by slightly pounding; the interior will only loosen by boiling; then there remains oblong white kernels or pips, from which fat can be extracted.

The belaban fruit are of the size of a coffee bean. In the shell are a few small kernels from which fat can be procured. These two fruits are never steeped in water, but simply dried.

The trees are not planted.

As with the madjau and terindak, the fruit fall for a part into the water, whence they are taken out by the natives. If the belaban fruit fall to the ground, it is not considered worth while to pick them up.

The proportion of fat in these two sorts is much below that of the tengkawang proper; the tallow of the belaban is moreover bad and soft, and only fit for burning. The minjak kelakki is fluid in all temperatures prevailing here, and when it is prepared with care, clear, of a sweet taste, so much so that it is even preferred for culinary purposes to tengkawang tallow. If, however, the fruit are allowed to germinate, the interior skin is apt not to disengage itself, and the oil becomes turbid or bitter.

These two fats are only made for private use and are not exported.

Of the tengkalak or malih a description is found in Van Gorkom's work "de Indische Cultures," Vol. II., p. 623 s. q. q.

I therefore only wish to observe that the tree does not occur here in a wild state, but always cultivated; also that no tallow is ever prepared from the kernels, or very seldom, and that the wood is quite worthless here.

This last circumstance is probably owing to there being plenty of good wood in these parts, while the reason for not extracting the tallow is that the number of trees is too insignificant, and the proportion of fat in the kernels less than the other fat-producing fruits.—*Indian Mercury.*

* According to an official writing of the Resident pro tem. of the Western *Afdeeling* of Borneo, 10,550 piculs were exported thence in 1856, and according to a later account of Prof. de Vriese the export from Pontianak alone, amounted, from the middle of 1858 to the middle of 1859, to no less than 9,953 piculs, representing on the spot a value of *f*232,595. "If you add to this" says the learned gentleman, "the exports from Singkawang, Sambas, Bandjermassing, an important annual total is obtained that slips from the Dutch trade to the great profit of the Singapore trade." Bisschop Grevelink, Planten van N.-Indie, bldz. 457.

Orange Shortcake.—Slice sweet oranges thin and sugar down about an hour before dinner. Prepare cakes as for strawberry shortcake, and place sliced orange between, pouring juice over each layer. Eat with or without cream, as preferred.—*Rural Californian.*

Warm Water for Plants.—This is indispensable for successful fruit forcing and plant growing, but which is not to be had in many gardens in quantity commensurate with the requirements. For plant watering, when such are in pots, enough may be drawn from the heating apparatus, or maybe there is a tank heated by a coil of pipes from the boiler available, but such supplies are perfectly inadequate when a Vine border 40 feet by 18 feet requires its 2½—3 feet of depth to be thoroughly soaked. Something more than tepid water is wanted to warm efficiently the cold manure-water, or other water, that must then be given, and the quantity altogether ought to be, at the lowest calculation, one gallon to the superficial square foot, which makes a total of 720 gallons, for a house of the size taken for exemplification; I would rather say 1,000 gallons, of which at least 500 would be manure-water when such would be given, the other 500 would require, for mixing purposes, to be brought up nearly to the boiling point, so that to keep the pot boiling in a way that would cause no cessation of the work, a boiler containing 100 gallons should be made use of, and this, if once got hot, would suffice by repeatedly filling it up. Such a useful thing could be placed in any shed or outbuilding, and would be found exceedingly handy for a variety of purposes. It has been discovered that warm water has a very renovating effect on soils that have been long in use in pots and borders—it also seems to be a means for purifying soured and almost infertile soils; this may be the reason that old window plants, such as Myrtles, are kept in such an enviable state of health, by the ladies who indulge these favourites with warm tea and coffee at times—the good results springing from the warm water itself, rather than from the theine or caffeine contained therein.—M.—*Gardeners' Chronicle.*

ROSE-WATER.

Ghazipore is famous for its rose-water and atar of roses. An area of about 160 acres is cultivated with the *Rosa damascena*, each acre containing about 1,600 plants. The outturn amounts to between 50,000 and 100,000 plants per acre, the price of which varies from 80 to 110 rupees per lak (10,000). The flowers are plucked in March and April, and the rose-water is distilled in the familiar but clumsy apparatus of the native distiller, the cultivator himself being rarely the manufacturer. A thousand roses will give a seer (2 lb.) of good rose-water, which sells at 1½r. Rose-water distilled a second, third, or even a fourth time fetches naturally a much higher price. The atar of roses is the only extract which floats on condensed distilled rose-water, exposed to the night air in a large copper vessel with a thin cotton cloth over it; and is collected in the morning with pigeons' feathers, and placed in phials. The phial is then exposed to the sun for a few days, and every particle of water evaporated; the pure oil, or atar of roses, thus left sells at 100r. to 125r. per tola (180 grains troy). This exquisite perfume is, however, only made to order, and the produce each year rarely exceeds 5 or 6 tolas. The ordinary bazaar atar is prepared by pounding sandal-wood, mixing it with water, and then distilling with roses in the usual manner. The best quality of this sells for 10r. per tola, while inferior sorts may be had for a fifth even of this price.—*Chemist and Druggist.*

THE USE OF NAPHTHALINE AS AN INSECTICIDE.*

Naphthaline, in one form or another, has for some time been used by entomologists as a means of preventing injury to their collections from acari, psoci, dermestes, anthreni, and other museum pests. My own experience is that it destroys the acari and psoci, but not the other pests, though it tends to repel them. Recent investigations would seem to indicate that it may be used to advantage in the field as an underground insecticide. It appears that as early as 1842 a French physician, Rossignon, pointed out the possible use of naphthaline not only as a remedial agency in medical practice, but also as a substitute for camphor for the destruction of museum pests. But up to the appearance of the grape phylloxera in France no serious experiments were made with it in the field. Among the substances tried against this pest naphthaline played its part. The efficient ingredient in the "poudre insectivore" of Peyrat, was, according to Maurice Girard, naphthaline; but the experiments with it did not yield encouraging results.

Baudet recommended it to the French Academy in 1872, while in 1874 E. Fallieres proposed gypsum saturated with naphthaline, the mixture to be distributed over the soil. It was also among the numerous substances experimented with by Messrs. Maxime Cornu and P. Mouillefert, the results of which were published in the well-known memoir presented by these gentlemen to the French Academy in 1877. Naphthaline, up to this time, prove to be of little value in killing the insect, and of no value as a repellant. Nevertheless, Dr. Ernst Fischer, of the Strassburg University, encouraged and induced by the most favourable results obtained with naphaline as an antiseptic and as a destroyer of micro-organisms (moulds, schizomycetes, bacteria, etc.), has, since 1881, again experimented with it as a direct remedy for the phylloxera, and he has given us the results of his experience in an interesting *brochure* lately received. The first part of Dr. Fischer's work treats of, and strongly recommends, the use of naphthaline for surgical purposes as an antiseptic superior, in most respects, to all other antiseptics now in use. His conclusions are based on extensive experiments showing the effect of the material on the lower organisms, and prove that, properly used, it not only arrests the growth of these micro-organisms but eventually destroys them. This part of the work will be of especial interest to those who are experimenting with a view of destroying disease-germs. It is to the second part that I would here call attention. Preliminary to a statement of the results of this part of Dr. Fischer's work a few facts in regards to the nature of the substance may not be out of place.

Naphthaline, a carbohydrate of the formula $C_{10}H_8$ was first made in 1820, by Garden, from coal tar. It is volatile at any temperature, melts at 79·2° C., boils at about 214° C., and has a specific gravity of about 1·1. Essentially insoluble in water, alkalies and diluted acids, it is easily soluble in ether, hot alcohol, hot concentrated sulphuric acid and in many volatile and rich oils. It is readily carried off with aqueous vapours, so that in order to quickly disinfect a room, it is only necessary to heat a vessel with water in which naphthaline has been put. The naphthaline gas mixes very readily with atmospheric air, and is also readily taken up by water. It is not poisonous to man or to the higher animals, and for surgical purposes should be used chemically pure. The crude material is by far cheaper, and upon inquiry Dr. Fischer found that in London it can be obtained, without barrels, at 25 marks (6 dollars) per 1,000 kilograms (about 2,200 pounds) in Paris at 100 francs, and in Cologne at about 45 marks (barrels included). The crude naphthaline contains more or less phenol and creasote, and is a stronger insecticide than the purified article, but also more injurious to plants. Dr. Fischer used the purified naphthaline in his experiments on phylloxera, but thinks that with some precaution the crude material might safely be used, especially if it is not brought in direct contact with the plant, or if used in the dormant season.

The experiments with phylloxerized grape vines were carried on under direction of Dr. Fischer at La Grave d' Ambares, near Bordeaux. Fifteen badly infested stocks* partly growing on light, partly on heavy soil, were treated in April, 1883.

It was placed in a hole dug in the ground near the main root, and subsequently covered up; and the quantity used was on some plants one, and on others one-half kilogram. On September 18th, the plants were examined with the following result:—All plants experimented with, but especially those treated with the largest quantity of naphthaline, showed a new and healthy growth of numerous long, fine rootlets, which were perfectly free from phylloxera; in fact, the phylloxera had entirely disappeared from the roots of all plants experimented with, whereas several plants not treated with naphthaline showed no young growth of rootlets, and an abundance of phylloxera. The growth above ground of the plants treated showed no difference as compared with plants not treated—a fact explained by insufficient time for the treated plants to recuperate. Some of the most vigorous new rootlets were found to have penetrated the layer of naphthaline, thus showing that the latter has no injurious influence upon them. A considerable quantity of the naphthaline was found unchanged at the date of examination, which shows that the evaporation is very slow, and that its effects will be correspondingly lasting.

The results are certified to by official affidavits, and were more marked on plants growing in heavier and moister ground than on those in light and gravelly soil.

As the most convenient mode of application, Dr. Fischer recommends that about 1 kilogram of the naphthaline be put in a trench dug around the plant a few inches from the stock; the trench to be not less than from 15 to 20 centimetres deep, and to be at once filled up again. He attributes the failure of former experiments: 1. To the small quantity of the material employed. 2. To its being employed too near the surface of ground, so as to permit evaporation in the air. He also thinks that results were expected after too short a lapse of time.—*Pharamaceutical Journal.*

CINCHONA CULTURE IN JAVA.—From the report which we have had translated and which appears on page 262, it will be seen that wild competition for *Ledgeriana* seed in Java had ceased, that a new fungus had appeared on the cinchona, and that attacks of *Helopetis Antonii* on Ledgers had been combated by arrangements made to capture the insects.

* 'Das Naphtalin in der Heilkunde und in der Landwirthschaft.' Von Dr. Med. Ernst Fischer. Strassburg: Trübner, 1883. Reprinted from the *Oil, Paint and Drug Reporter*, May 14, 1884.

* It is not stated whether the roots of these stocks were examined at the time, to ascertain whether or not the phylloxera was still at work.

INDIAN FORESTRY.

The following note has been drawn up by Sir George Birdwood, to accompany the exhibition of Indian forest produce in the International Forestry Exhibition, Edinburgh:—

It may be said that forest conservancy in India originated in Edinburgh. Roxburgh, Wallich, Royle, and others of the early explorers of Indian botany, long ago called attention to the destruction which had being going on for centuries of the forests of India and Burmah. In primeval times India, as is evident from the descriptions given in the Ramayana and Mahabharata, was covered with dense forests, the productions of which found their way into the commerce of antiquity long before the name of India itself became generally known. Thus most of the costly spices used for embalming the dead in Egypt, and by the Jews in the service of the Tabernacle at Shiloh and Jerusalem, must have been received from India. Recently, also, it has been discovered that Indian Teak was used in the building of the temples of Babylonia, although it is uncertain whether it was employed in their original construction during the period of the first Chaldean kingdom, from about the thirteenth to the twentieth, and possibly thirtieth century B.C., or in their restoration during the Babylonian empire of Nebuchadnezzar, in the seventh century B.C.

In the course of the gradual occupation of the valley of the Indus and of the Jumna and Ganges by the Aryan race, and of Southern India by the Dravidian races, the alluvial plain of Hindustan, and the upland basaltic plain of the Deccan became partially deforested; but primeval forests still covered all the southern slopes of the Himalayas, and the mountainous coasts of Malabar and Coromandel, and the wide hilly region of Central India, north and south of the Nerbudda and Taptee rivers, still known by the name of Gondwana, "The Gond Forest."

It was in the troubles following the decline of the Moghul empire that these remaining forests were gradually encroached on, and vast extents of the surface of the country converted into wild wastes; and it was the destruction of vegetation over wide extended areas at this time which thenceforward rendered India liable to desolating droughts, and the consequent calamity of often-recurring famines.

Where the British Government first felt the pinch was in the increasing difficulty found in providing timber of the required scantling for shipbuilding; and with the view of keeping up the supply of Teak for the Government dockyard at Bombay, the late Dr. Gibson, of the Medical Establishment in that Presidency—where he was long known to the passing generation by the affectionate soubriquet of "Daddy Gibson"—was appointed in 1846 Conservator of Forests. Such was the state of things in India, when, in 1850, the British Association, which met in that year at Edinburgh, appointed a committee to report on the probable effects of the destruction of tropical forests, and the report was presented in the following year, when the Association met at Ipswich. The broad view taken of the subject in the report, and the weight of the facts brought forward in illustration of the immense importance to the economy of civilisation of the conservancy of the forests of the tropics, attracted the attention of the Court of Directors of the Honourable East India Company, and within a few years afterward regular forest conservancy establishments were sanctioned for the Madras Presidency and British Burmah.

Before 1848 no check whatever had been imposed in India on the reckless clearing of the primeval forests for cultivation, and no heed was taken of the effect of such clearing, particularly on the slopes of hills, would have on the rainfall. In 1848 Major-General Frederick Conyers Cotton, C.S.I., then a captain in the Madras Engineers, urged on the Madras Government the necessity for taking some immediate steps to preserve the forests bordering on Coimbatore and Cochin from further denudation by the reckless wastefulness on the native contractors who farmed the forests for the supply of Teak-wood for the Bombay dockyard. On his recommendation Colonel (then Lieutenant) Michael, C.S.I., who had had opportunities of observing forest conservancy on the continent of Europe, and who, as an accomplished *shikari*, had a wide practical acquaintance with the forests of Southern India, was appointed to give effect to General Cotton's proposals. Colonel Michael organised an establishment, opened out roads and timber slips down the mountain passes, and soon scored a financial success. His efforts in providing efficient conservancy were far more important. It became at once apparent that it was better in the interests of the State to preserve the magnificent natural forests of the Presidency than to raise an immediate revenue from them; and the first step taken in this view was to lease an extensive Teak tract from the Zemindar of Colangode, and to buy up all his minor contracts with timber merchants. The whole of the southern forests in the Madras Presidency, down to Cochin and Travancore, were thus placed, and have ever since remained, under strict conservancy. A system of clearing belts of brush-wood to preserve the young saplings from fire was also introduced, the hill tribes being employed in the work; and in this way the destruction of the principal forests of Southern India was most opportunely averted.

Within a few years the advantages of these measures, and the great success of Colonel Michael's work, were so clearly seen, that the court of directors, who had just then been so strongly impressed by the report of the British Association, sanctioned the extension of General Cotton's scheme to the remaining forests in the Madras Presidency, and, in short, inaugurated the organisation of the regular forest department, not only in Southern India, but for the whole Indian peninsula and British Burmah. About the same time Colonel Michael, whose health had been undermined by seven years of incessant exposure to the dangers of forest life, when little was known about healthy or unhealthy seasons in the jungles, was forced to retire from his appointment, the work of which was taken up by Deputy-Surgeon-General Hugh Cleghorn, M.D., as the first regularly constituted Conservator of Forests in the Madras Presidency.

Cleghorn carried out the organisation of the new department in Madras with such astonishing energy and success that he was soon called on to extend the sphere of his operations into the Punjaub. He also afforded Dr. Brandis, C.I.E., the most efficient assistance in introducing and systematically working conservancy in the forests of Bengal, and with the most satisfactory results. Brandis had previously done very distinguished forest work in Burmah, and in 1862 was appointed Inspector-General of Forests under the Government of India. From that time the successful future of forest conservancy in India was assured. The eminent scientific and administrative abilities of Dr. Brandis have been widely recognised; and to him we owe the introduction of the Indian Forest Acts, which, while strengthening the hands of the Government, have secured to the people the maintenance of all the ancient rights and privileges inherited by them from time immemorial.* He, in fact, by his great capacity, his wise recommendations, and his personal example of enthusiastic devotion to duty, has made the Forest Department of India what it now is.

The cost of the three establishments (including Bengal and Burmah), Madras and Bombay, in salaries, travelling allowances, contingent expenses, &c., is £190,000 per annum.

The Forest Acts, originated by Brandis, arose out of the necessity of giving a legal status and legal authority to

* One of the main difficulties with which the Forest Department almost throughout India has had to cope is that of the customary privileges of common. The people, especially the agriculturists, have for generations been accustomed to use the forests for cutting firewood, grazing, and even clearing for cultivation, without restriction. The exercise of these rights, without regulation, was tending to the certain destruction of the forests, and, with the rapid increase of population under the British Government, was every year becoming more injurious to the public welfare. It was, therefore, absolutely necessary to bring the Indian forests under some control; while at the same time it was felt that to suddenly prohibit the traditionary rights of the people in them would be most cruel and unjust. What, therefore Brandis aimed at in his Acts was to forbid altogether the exercise of those privileges which were incompatible with the existence of the forests, and to allow others to as great an extent as possible. Thus in every locality some of the forest land is still left open to grazing and firewood cutting, &c., and some strictly closed for a period long enough to enable the trees on it to recover.

the new department. There are at present three of these Acts, viz., No. VII. of 1878, which applies to India generally, including Bombay; No. XIX of 1881, which applies to British Burmah only; and No. V. (Madras) of 1882, which applies to the Madras Presidency. They are all based on the same principle, and do not widely differ in details. Speaking broadly, they divide the forests of India under three select classes—Reserved forests, protected forests, including Vellore forests, and forests which are private property.

The reserved forests are under the direct control of the department, and are managed exclusively as a source of immediate and prospective profit, their limits being surveyed and demarcated, nomadic cultivation within them forbidden, destructive undergrowth cut out, the annual hot weather fires guarded against, and the cutting of timber strictly regulated. The protected forests are subject to less stringent supervision, and the people retain therein, subject to regulation, their hereditary rights of cultivation, pasturage, and wood cutting; only certain kinds of timber being protected. Private forests are controlled only to such an extent as is necessary to prevent their destruction. Besides these there are the State plantations devoted to the cultivation of timber trees.

The area of the reserved forests of India is about 46,000 square miles. That of the unreserved forests has not yet been ascertained, while that of the plantations under the Government of India and Madras alone is 11,000 acres. The area of the plantations in Bombay is not known; but it is stated that the great problem of Indian forestry, viz., the re-wooding of waste districts, has been grappled with in the western Presidency with great vigour and success, by sowing broadcast the seeds of all sorts of forest trees and shrubs, the result of which action is now beginning to be seen in the appearance everywhere of "countless millions" of vigorous saplings. Extensive fuel reserves have also been provided, and are strictly preserved in all parts of India, to meet the extension of railway lines throughout the peninsula.

The nett revenue derived from these operations, after deducting all charges for salaries and working expenses, now amounts to over £300,000. Prior to 1848 the revenue from the Indian forests was nominal, and there was no forest conservancy.* And this vast and beneficent change, which will gradually also reduce droughts and famines in India to a minimum, has been achieved in a single generation, or in the brief space of thirty-five years.

We have an illustration in Northern Afghanistan of how misgovernment may convert a once fertile and wealthy country, such as Afghanistan was under the commercial rule of the Buddhists, into an inhospitable desert, and all India, within the solstitial line, would probably have by this time been reduced to the same condition but for the English conquest of the peninsula.

When about ten years ago Mr. Griffin W. Vyse was executive engineer at Dheera Ghaza Khan in the Punjaub, he planted over 1,000,000 timber trees along the frontier joining India to Afghanistan and Beloochistan, and scattered five tons of their seeds broadcast everywhere; and in 1877 at least 50 per cent of these seeds had sprung up into flourishing young trees. Great zeal was also shown by Mr. C. E. Gladstone, who was an assistant commissioner in the Punjaub at this time, in encouraging the planting of trees along the base of the Suleiman range. The Punjaub Government have also formed a forest of trees several miles in extent at Chunza Munza, near Lahore; and the result of all this planting on our Indian north-west frontier is already being felt in the gradually increasing annual rainfall in the Southern Punjaub, Southern Afghanistan, Northern Beloochistan, and Northern Scinde. When these results become more marked, and extend further into Afghanistan, the predatory character of the population of that country is sure to be stroogly modified; and should Russia adopt a wise system of forest conservancy in Turkestan, we may hope for the gradual restitution to the whole of Central Asia of the prosperity it once enjoyed.

The planting of trees has always been a highly honoured popular custom among the natives of India, and the Brahmins have a saying, wisely devised to encourage the practice, that "He who plants a tree lives long." We may augur, therefore, from the success of our forest department, a long life to British rule in India.

It is a happy omen also that the first International Exhibition of Forestry should have been appointed to be held in the stately capital of Scotland, where scientific forestry throughout the British empire received its earliest impulse—and that the exhibition should be so much indebted for its prosperous issue to the co-operation of Colonel Michael, the pioneer of practical forestry, and of Cleghorn, the father of scientific forestry in India.—George Birdwood.—*Gardeners' Chronicle.*

* Before 1848 the forest revenue, which was treated as a branch of the land revenue, was very trifling. In 1867-68 it amounted to £331,000. In 1881-82 it amounted to over £874,000; and as the total charges under all heads amounted to £557,000, the nett forest revenue was exactly £317,000. It must, however, be borne in mind that, even from a financial point of view, the annual revenue which forest conservancy has as yet provided is utterly insignificant when compared with the capital value of the Indian forests redeemed by the British Government from certain destruction.

ESSENTIAL OILS: THEIR DERIVATIVES AND SOME OF THEIR USES.

(Continued from p. 888, Vol. III.)

Part II.

Paper read before the Chemist's Assistants' Association by Mr. William A. Wrenn, March 19, 1884.

In the first part of this paper (*vide The Chemist and Druggist*, December, 1883, page 598) I alluded to those essential oils for the production of which the English distiller has obtained the foremost place, and that are also of therapeutic value. I have now to notice those essential oils which are more or less aromatic, and, perhaps, less used in medicine.

Oleum Amygdalæ Essentiale.—By far the larger quantity of this oil is of foreign distillation. There are a few houses in London whose products to a certain extent enjoy a monopoly and command a long price, and justly so, as foreign importations have always been regarded with suspicion, on account of many sophistications.

Amygdalus communis (var Amara) is cultivated in the South of France, generally in conjunction with *Olea Europæa*. I noticed very extensive plantations in Provence, and particularly along the road leading from Marseilles to Aix and Avignon. Morocco and the North-east of Africa, Barbary, Sicily, and Spain, and the country to the north and east of the Persian Gulf furnish a considerable supply.

Sicily and Barbary "bitters" are generally pressed in London for the fixed oil. The dry almond-cake is broken up with water and quickly placed in the still. Hydride of benzoyl (ol. amygdal. essent.) is distilled over, combined with hydrocyanic acid.

Glucose is also formed, and remains in the still. The equation descriptive of the action is given thus in Attfield's "Chemistry":—

$$\underset{\text{Amygdalin}}{C_{20}H_{27}NO_{11}} + 2H_2O = \underset{\text{Benzoic aldehyde}}{C_7H_5OH} + HCN + \underset{\text{Glucose dextro anhydrous}}{2C_6H_{12}O_6}$$

The product varies from ·4 to ·95 per cent from the almonds themselves, which corresponds to from ·75 to 1·6 per cent of essential oil from the almond-cake, the expressed oil being yielded to the extent of about 43 per cent.

The crude essential oil has a specific gravity varying from 1·056 to 1·070, and some very old samples gave sp. gr. of 1·078 and 1·080 respectively; in the latter case the oil was dark in colour, with a distinct smell of benzoin.

It is very important that the proportion of hydrocyanic acid with the essential oil should be noted. It varies from 8 to 12 per cent. Acid, hydrocyanic dil. B.P. contains but 2 per cent. The highly-dangerous properties of the crude oil are, therefore, obvious, and necessitate extreme caution in its distribution and application.

There are several methods for depriving the oil of its prussic acid. The process generally adopted commercially is to treat with ferrous sulphate dissolved in water, and add lime to excess of alkalinity. After contract for a short time the oil is re-distilled, deprived of the water

by separation, and finally dried by means of anhydrous calcic chloride.

This process requires considerable care and the avoidance of high temperature. The loss in purification varies from 8 per cent to 10 per cent; and, unless the oil is well dried by calcic chloride, oxidation is quickly set up, and large masses of crystals of benzoic acid are formed. I have observed, in course of business, a bottle to go entirely solid, except a thin stratum of a very limpid fluid entirely destitute of the odour of almonds.

Distillation with red oxide of mercury, after a few days' occasional agitation, is a very handy method for small quantities, and the following data may be useful:—

Take a small retort (tubulated and stoppered), pad it round with asbestos, and place in a cradle of iron gauze. Half fill the apparatus with the oil, which has been allowed to remain in contact with red oxide of mercury in sufficient quantity to cover a possible 12 percentage of hydrocyanic acid, insert a thermometer through the stopper, and regulate the heat at no time to exceed 280° Fahr. The cyanide of mercury may be re-converted to the metallic state.

The purified oil should be of sp. gr. 1·049 to 1·051.

Analysis of Trade Specimens.

Nos.	Sp. gr.	Loss in Volume when treated with water Per Cent.	Solidified.	Boiled.
1...	1·068	1·05	Slightly at 32° F.	291° F.
2...	1·056	0·725	„	283° F.
3...	1·061	0·75	„	286° F.
4...	1·078	1·25	„	294° F.
5...	1·080	1·25	„	295° F.
6...	1·065	1·00	„	285° F.
7..	1·063	1·65	„	283° F.

Sample No. 7 was slightly turbid, and had not been sufficiently dried.

The adulterations generally sought for, and in some cases found, are the artificial oil nitro-benzole, or essence of myrbane and alcohol. The pure oil gives a blood-red colour with acid sulphuric and nitric acid (1·420); no action at first, but subsequent deposition of crystals of acid benzoic.

Table to Detect Impurities.

	Sp. gr.	Loss in Volume when treated with water Per Cent.	Solidified.	Boiled.
Oleum. amygdal. essent., crude	1·068	1·05	Slightly at 32° F.	291° F.

* Slight odour of tar.

From the above it will be seen that the samples were very uniform. I do not attribute the characteristics of No. 4 to any sophistication, but probably, when the original bottle was opened, some of the black sealing-wax became mixed with the oil. Original bottles of cajuput oil are corked with a piece of reed or soft bamboo, and waxed at the end.

I have a sample of oil which has been thrice re-distilled from phosphoric anhydride. The camphoraceous odour has been removed and that of hyacinths substituted. This is due to a principle termed cajaputene. The oil is used externally as a stimulant, and is sometimes administered internally in certain cases of cholera.

Copper was proved to be present, first by treating the oil with a little weak solution of ammonia; upon standing, the oil was left colourless, and the aqueous solution blue.

Second test: After evaporating some of the oil to dryness, the residue was dissolved in nitric acid, and tested for copper with ferrocyanide of potassium.

Oleum Caryophylli, distilled from the flower-buds of *Caryophyllus aromaticus*.

The cloves on the market vary as much in their source as in price—Amboyna, Penang, Mauritius, Zanzibar, Java, Réunion, &c. Most of the oil of English commerce is obtained from Zanzibar cloves and stalks. The islands to the east of Zanzibar furnish some very good samples of cloves, and the island of Seychelles has also exported some oil of very good quality. The oil obtained from Germany is also principally from Zanzibar cloves. The yield varies from 12 to 22 per cent.

Commercial Samples.

No. 1...	English	...Sp. gr.	1·056...	Pale straw colour
„ 2...	„	... „	1·057...	Straw „
„ 3...	German	... „	1·048...	„ „
„ 4...	„	... „	1·052...	Pale straw „
„ 5...	„	... „	1·050...	Reddish-brown colour
„ 6...	From stem..	„	1·046...	Brownish „

The oil distilled from clove stems may be distinguished from that obtained from the flower-buds by giving a deep violet colour if shaken up with metallic iron.

The true oil is very soluble in alcohol, and castor oil, if used to adulterate it, will be first thrown out upon diluting the alcoholic solution with water.

If caustic potash be added to the alcoholic solution the oil is converted into a crystalline solid, destitute of the true odour of cloves.

Some months ago a sample of clove-water was shown me, which after standing gave a precipitate. It was investigated by a member of this Association, Mr. F. H. Alcock, and found to be eugenate of lead. The presence of lead is accounted for by the fact that the worm of the condenser was not of block tin, or was a mixture of tin and lead. It would be of interest to know to what extent eugenic acid is capable of acting on the various metals.

The colour of oil of cloves deepens considerably on keeping, and also becomes denser on long exposure to the air, due to evaporation of the lighter (sp. gr. ·920) of the two oils, the sp. gr. of the heavier oil being as high as 1·080.

Oleum Copaibæ Essent.—A colourless or slightly greenish oil, yielded by copaiba, in quantity varying from 36 per cent to 60 per cent.

The Para balsam yields by far the largest proporation of oil and has the best aroma. It is necessary to take into reckoning the age of the balsam.

The sp. gr. varies from ·878 to ·900.

The largest proportion of the oil found in commerce is practically a bye-product from those wholesale houses who make a specialty of liquor copaiba soluble, with its long string of compounds, existing in some cases more on the label than in the preparations.

The slight green noticed in some samples is produced by the use of copper vessels in manufacture.

Its relative solubility in alcohol will determine the presence of turpentine.

The boiling-point of oleum copaibæ is a very high one, about 500° Fahr.

The dose is from 5 to 20 minims, but the oil is but little used in comparison with the balsam itself.

OLEUM CUBEBÆ.—This is distilled from the fruit of *Cubeba officinalis*, cultivated in Java and imported into this country from Singapore. This drug is causing some sensation in the market, owing to the extraordinary prices now ruling, viz., 18*l.* per cwt.

The great scarcity is attributed to the large demands from America, where cubebs are extensively employed in catarrhal affections of the air-passages, in inflammation of the bronchial tubes and the intestinal canal. Oxide of bismuth is given in conjunction with advantage.

The product of oil from the fruit is about 7 to 12 per cent.

I have only examined two samples, one of English distillation, and the other from a well-known German house.

No.	Sp. gr.		
1...English ...	·929...	Pale green	...Soluble in 17 pts. alcohol
2...German ...	·924...	greenish brown	,, 18 ,,

When adulterated with oil of turpentine its solubility in alcohol is lessened.

Submitted to fractional distillation oil of cubebs yields one oil sp. gr. ·915, and a more dense one of sp. gr. ·937.

If upon evaporating a sample upon a piece of paper an oily stain is left, the presence of castor oil is indicated. The oil is turned red by sulphuric acid, brown by nitric acid.

OLEUM JUNIPER, BACC.—This oil is distilled from the fruits (galbuli) of *Juniperus communis*. The yield of oil from the unripe fruits is about from ·25 to ·5 per cent, and from ripe fruits ·5 to ·2 per cent. The sp. gr. varies from ·865 to ·880. I wish to draw attention to this oil, and to distinguish it from the oil distilled from juniper wood.

No.	Sp. gr.		
1 Oleum junip. bacc....	·870...	Colourless...	Warm aromatic taste
2 ,, wood...	·860...	,,	...Terebenthinate ,,
1 ,, bacc....	soluble in 12 parts alcohol with turbid solution		
2 wood ,,	...	,, ,,	clear ,,

The oil from the wood did not cause an explosion when treated with metallic iodine, as was the case with ol. junip. bacc.

Oleum junip. bacc. submitted to redistillation leaves a resinous residue in the still.

It is very difficult to test between these two oils, both of which, upon long keeping, acquire the odour of turpentine. The nasal organ is the most reliable test for newly-distilled samples.

With its uses we are all acquainted, but it should be mentioned that the oil has recently been tried with success as a substitute for guaiacum as a diaphoretic.

A very pretty test for oil of juniper is to add to it a few crystals of hydrate of chloral; after standing a short time the colour changes from yellow to brown, and subsequently to green.

OLEUM SANTAL. FLAV.—It is to be regretted that this oil is not enumerated in the British Pharmacopœia, occupying, as it does, such an important place in pharmacy, and to a limited extent in perfumery

The following samples were examined:—

No. 1 ...	English distillation	...	·952 pale yellow
2 ...	,,	...	·948 yellow
3 ...	German distillation	...	·948 dark yellow

The last, which was distilled from East Indian wood, when re-distilled gave a much paler oil—sp. gr. ·945—a resinous residue remaining.

OLEUM SASSAFRAS.—I think this oil with advantage might replace the raspings used in the preparation of compound decoction of sarsaparilla, dissolved in a little spirit, as certainly the largest part, if not all, must be driven off in the boiling. Two drachms would be the equivalent of 10 lb. of wood.

All samples below sp. gr. 1·090 should be rejected. By adding sulphuric acid in excess the oil is completely charred. Shaken up with water, the oil is separated into two oils, one lighter and the other heavier than water. Nitric acid converts it into a red resin.

OIL OF WINTERGREEN.—In conclusion, I wish to make a note of the two varieties of wintergreen oil. The American source—*Gaultheria procumbens*—yields the heaviest of all essential oils (sp. gr. 1·180). The oil from the East Indian source—*Gaultheria punctata*—is not so powerful in odour as the American oil, and the sp. gr. is 1·155. The sample of this oil, only recently placed in my hands, has not yet been thoroughly examined.

N.B.—In all references to solubility in alcohol that of sp. gr. ·838 is intended.

The boiling-points were taken in a bath of solution of acetate of soda. Those higher than 250° F. in olive-oil bath.

I also tried the U-tube and mercury, but did not obtain constant results.—*Chemist and Druggist.*

GUTTA-PRODUCING TREES.

[The following interesting paper upon the trees which produce the "Gutta-percha"* of commerce has been placed at the disposal of the Society by the courtesy of Sir Frederick A. Weld, to whom it has been submitted by Sir Hugh Low, Resident of Perak.]

Sir Hugh Low, Resident of Perak to the Hon'ble the Acting Colonial Secretary, Straits Settlements, dated The Residency, Thuipeng Larut, 12th October 1883.

SIR,—I have the honor to forward, for the information of His Excellency the Governor, a Report on the trees producing the "*gutta percha*" of commerce, by Mr. L. Wray, Junr., Curator of the nascent institution which, it is hoped, may develop into a useful collection of the natural products of this State as the Perak Museum.

The collections, when at the commencement of the current year His Excellency appointed Mr. Wray, were in a very embryonic state, and being aware of the careful habits of observation he had acquired as an amateur of considerable attainments in electrical and chemical science, and of his zealous pursuit of scientific knowledge in other directions, I requested him to devote his attention to collecting information as to the valuable product known as "*gutta percha*," together with complete series of specimens of the product, and the trees which produced it, such as might enable the eminent men of science at the head of the Royal Institutions of Kew, Ceylon and Calcutta to botanically identify them.

3. Mr. Wray has zealously and successfully carried out the instructions he received, and complete specimens of several species have been made available, and their receipt cordially acknowledged, and others are in course of preparation.

4. In addition to this, Mr. Wray's scientific training has enabled him to discover that, by the wasteful means of collecting, which alone have been hitherto practised, by far the greater part of the valuable product for which the tree is destroyed remains in the bark which is left to rot in the jungle, so that not more than the merest fraction is made available for the demands of commerce.

5. The process necessary for extracting the whole of the gutta, Mr. Wray describes as simple maceration of the fresh bark shred into thin slices, or of the bark dried and pounded, a process so productive of valuable results that he considers the quantity exported from the Straits Settlements might have been gathered from one-thirtieth of the number of trees which, it is estimated, must have been destroyed to produce it.

6 In Perak, the larger trees had been destroyed before

[* The unknown person who first rendered the Malay word *getah* (sap, gum, bird-lime) by the Latin word *gutta*, deserves credit for some ingenuity. The accidental resemblance of the two words, and the adoption of the latter by botanists, may however be misleading as to the true derivation of the term "*gutta percha*." *Getah*, in Malay, is the generic term for any kind of sticky sap which exudes from trees, plants, leaves or fruit: *percha* means a rag, bit or strip of any stuff. *Getah percha* would thus mean *getah* in strips or pieces (after being boiled), as opposed to the semi-liquid and sticky condition of the raw substance.—ED.]

my attention was attracted to the manner in which it was collected. The quantity exported was rapidly diminishing, when in 1880, I advised the Government, as the only means of preventing the annihilation of the species, the young trees of which were being rapidly cut down, to forbid the export altogether.

7. Old trees had become so scarce that we had great difficulty in securing flowering and fruiting specimens, and I have, as noticed in the diary of my late expedition to the upper waters of the Perak River, ascertained that the central parts of the Peninsula cannot, in all cases, as has been supposed, be trusted to produce an inexhaustible supply. On the light sandy soils which prevail there, none of the "*getah taban*" trees are seen, and the natives assured me that although the kinds of Indiarubber called "*getuh rambong*" (*Ficus elastica*) and the "*getah sengyâriр*" (*Willoughbeia*) had been common, the *Dichopsis* or *Isonandra* and the *Payena*, which is nearly of equal value, were quite unknown. These were, however, very common on the ranges of mountains near to the Straits of Malacca and on the lands bordering the sea-coasts, where the climate is much more moist and the soil is a stiff clayey loam resting upon granite, while the lighter soils of Upper Perak are on slates, schists and other metamorphic rocks.

8. As the more economical mode of dealing with the product of the "gutta" trees brought to notice by Mr. Wray—collecting the bark instead of the gum—will be of great importance to such States as still have a supply, I would recommend that Mr. Wray's Report be published in the Straits Settlements *Government Gazette* or in the Straits Branch of the Asiatic Society's Journal, so that, what there seems no reason to doubt, is a valuable economic discovery, which it is quite likely may be equally applicable to other gums or Indiarubber-bearing trees, may be made known as widely as possible. It might even, with advantage to the commerce of the Straits Settlements, be translated into Malay.

HUGH LOW,
Resident, Perak.

Mr. L. Wray, Jr., to Sir Hugh Low, Resident of Perak, dated the 25th September, 1883.

SIR,—I have the honor to inform you, that in pursuance of the request you made some months ago, I turned my attention to the study of those trees from which the Gutta Percha of commerce is procured; and I now beg to present to you my Report, embodying the result of those studies up to the present time; and solicit your special attention to that portion which relates to my discovery of the large quantity of Gutta Percha that may be extracted from the bark, which is now entirely wasted.

I have sent botanical specimens, and, in most cases samples of gutta and wood, of nearly all the trees I have mentioned, to the Royal Gardens at Kew, and also to the Royal Botanic Gardens, Calcutta, and the Royal Botanic Gardens, Ceylon; so that when the eminent botanists at those establishments have examined and compared the several specimens, the mystery in which their botanical identification has been hitherto so completely enshrouded will, I venture to hope, be satisfactorily solved.

Getah Taban Merah (Dichopsis Gutta, or Isonandra Gutta.)

This tree, from which the best kind of Gutta Percha is obtained, grows, or rather used to grow, throughout the jungles of the plains of Perak and a short way up the sides of the hills.

It seems to like a considerable amount of moisture, and will even grow with its roots in a running stream. It is a tree of large size, attaining a diameter of 4 to 5 feet, and a height of between 100 and 200 feet.

It has large thin buttresses around its base, which often present, on their upper portions, a convex profile, and, on a large tree, attain a height of 6 to 8 feet, and a span at the base of 4 to 5 feet from the trunk. As far as I have yet seen, they never form an arch, but have their lower parts buried in the earth, from the trunk to their extremities.

When growing in the forest, the tree has a clean, straight appearance, the former being due apparently to the bark peeling off in irregular pieces. The bark is of a rich brown-red colour, and from one-third to half an inch in thickness. Inside the epidermis it is of an Indian-red tint; and when cut, the milk white sap oozes out, at first in small beads, which, enlarging, soon join and covers the injured part with a coating of a cream-like consistency. The leaves are lanceolate on a young tree, and roundish oval with abrubtly acuminiative points on a tree of mature growth. The margin is entire, and they are covered on their under-surface, with minute silky warm-brown hairs. The leaf stalks and young wood are also covered in a similar manner, which gives the whole tree, when looked at from below, a brownish tint, by which the tree may generally be recognised. The upper surface of the leaf is dark green, and the veins are not prominent. The calyx consists of six sepals, three of which are superior to the others and alternate with them.

They are coated, like the backs of the leaves, with silky-brown hairs. The corolla is white, and is divided into six petals. The style, which is simple, is sometimes persistent, and may be seen on the ripe fruit. There are six ovules, but one or two seeds only arrive at maturity.

On the apex of the young fruit, the six carpels of which it is formed can be distinctly traced. The fruit is coated, like the backs of the leaves, with brown down; its flesh is soft, and it is sweet, but it has a disagreeable flavour of gutta percha.

The seeds are very oily, and they are, together with some of the seeds of nearly allied species, collected by the Malays and the Sakais, who dry them in the sun for some days, and then express the oil by putting them between two flat pieces of wood, and applying pressure by clamps and wedges.

The oil, which is solid at the ordinary temperature (that is up to 90°), is highly esteemed for cooking purposes. Birds, squirrels, monkeys, &c., are very fond of the fruit and of the seeds, which adds to the difficulty of obtaining them.

It flowers in the month of March and ripens its fruit in June; but the Malays assert that it only fruits once in three or four years.

The gutta of this variety is red, and the colour is not due to an admixture of bark as is frequently stated. It is probable that other varieties of gutta may be sometimes mixed with bark to make them look like *Taban Merah*, and so command a higher price than they otherwise would; but the true *Getah Taban Merah* is red *per se*, and the water in which it is cleaned, although changed many times, still becomes deeply dyed with that colour. Specimens of this, in fruit, together with wood, bark, and gutta, I sent to the Royal Gardens at Kew, Calcutta, and Ceylon, on May 30th, 1883.

Method of collecting the Getah Taban Merah.

A tree having been found, a staging of saplings tied together with roots or rattans is erected round it, so that it can be cut above the spreading buttresses. The tree is then felled with a little Malay axe called a "*beliong*," and as it lies on the ground, V shaped rings, about one inch broad, are cut in the bark, at intervals of 15 to 18 inches, all along the whole length of the trunk, and of the large branches, with a heavy chopping knife, called a "*parang*." These cuts soon become filled with the white cream-like sap, and in about half an hour the gutta will have separated from the aqueous portion of the sap, and may then be removed by rolling a small ball of it round in the cuts, to the edge of which the coagulated gum adheres and forms a disc, varying in size according to the number of scores it is rolled in.

These discs are then boiled in water and made into balls, and sold by the collectors to the men who export it to Penang or Singapore.

The gutta is at first pure white, but soon changes to pink, and finally to a brownish-red. The water in which the gum is boiled becomes a dark red-brown, and this colouration is the most distinctive feature that this variety of gutta possesses, and by which it may be easily recognised.

The air seems to have on the sap an effect analogous to that of rennet on milk, coagulating the gummy portions so rapidly, that only a small quantity of their watery stuff runs out of the cuts, all the gutta percha remaining as a soft spongy mass in the scores.

The amount of gutta obtained from a single tree appears to have been greatly over-estimated in the accounts that

have been written on the subject; and exceptionally large yields from gigantic trees have been erroneously quoted as being an *average* product, which is clearly by no means the case.

I had a tree felled, that was two feet in diameter (at six feet from the ground) and about one hundred feet high, the age of which I estimated, from its annular rings, to be over one hundred years. It gave only 2 lb. 5 oz. of fairly clean gutta, valued by a Malay dealer at $1·20 per catty or 3s. 3d. per lb., so that the product of this tree was worth only 7s. 6d.

Some say that if gutta trees are felled in the height of the rains and when the sap is rising strongly, they then yield more gutta than at other times; but I have had no means of testing the truth of this assertion.

Getah Taban Sutra. Dichopsis* ——.

This tree is usually confused by the Malays with the preceding one, but is very different to it in many respects It grows on low hills, and the Malays say will only thrive in sight of water; and those I have seen certainly bear out this idea, for they were all near the bank of some stream, and at an elevation of about 500 to 600 feet above sea-level.

It has much the same appearance as the *D. Gutta*, but the leaves are smaller, and their backs have a yellower shade of brown, and the buttresses are much smaller, and have a concave outline. The bark, which is dark brown, is smooth, and shews by smooth oval indentations the places where the branches have been when the gutta was young. This is a feature I have not noticed in any other gutta, and may, I think, be taken as characteristic.

The flowers have a reddish tinge, and the fruit is coated like the backs of the leaves, and is oval in form, and about the size of a mussel plum.

Its gutta is pale reddish-brown (like *Getah Sundik*) and the water in which it is boiled does not acquire a red colour. It coagulates nearly as quickly as *Taban Merah*, and is collected in the same way.

The specimens I collected were obtained from the Ulu Kenering, Perak. The tree was 12 inches in diameter at 3 feet from the ground and was in fruit when felled on the 17th August, 1883. The flower was obtained by a Malay about ten weeks previously.

Getah Taban Puteh (White). Dichopsis Polyantha?

This tree cannot be told, by its outward appearance, from *Dichopsis Gutta*, except that its leaves are rather larger.

It has large buttresses, with convex tops, and the bark is nearly of the same shade, but rather browner. The fruit also seems to be similar, and the flowers are white; so that it is not until the tree is felled, that any very distinctive character appears. It is then found that the sap, which is much more copious, does not coagulate quickly, and when it does, it is of a dirty white colour, and has a much higher softening point than any of the higher kinds, even boiling water not being sufficiently hot to thoroughly soften it. This tree grows on the hills up to an elevation of 2,500 feet above sea-level.

I have never seen it growing on the plains, nor in fact lower than 1,800 feet.

It ripens its fruit in the month of February.

The gutta is collected by felling the tree, ringing the bark, and placing leaves, bamboos, &c, under it to catch the sap; which is afterwards boiled, and the natives often add salt to hasten its coagulation.

It is frequently adulterated with the gutta from Kayu Jelutong, and two or three of the Bassias.

The usual method of mixing them is to do so before the sap has coagulated, as afterwards, owing to the high melting point of *Taban Puteh*, they cannot be so easily and intimately combined. A tree of ten inches of diameter at four to five feet from the ground, gave 2 lb. 11 oz. of fairly clean Gutta Percha.

Getah Taban Puteh (Variety).

This variety differs from the above in having smaller leaves, and in the shape of the fruit, which is longer in proportion to its breadth.

I have found it growing on the hills at 2,300 feet elevation, and it ripens its fruit in the month of February.

* Sutra=silk.

Getah Taban Chayer. Dichopsis* ——.

This tree I have found growing at 600 feet above sea-level, and it attains a large size.

The bark is reddish brown, and the wood is hard and white, with a dark red centre.

The backs of the leaves are, when young, of a golden brown, but full grown ones are silvery.

They have not the points of the leaves that are present in most other varieties of Dichopsis.

The flower, which appears about the middle of September, is pale green and very small.

The corolla has a six-toothed limb, the teeth being nearly triangular in shape, and so thin as to be almost transparent.

The diameter of the flower is about 3-16th of an inch.

In the throat of the corolla are inserted, by short filaments, twelve anthers. They are placed alternately in the centre of the teeth, and at the junction between two teeth.

The style is simple, and of such a length that it projects beyond the petals, in an unopened flower bud. It appears to be often persistent.

The gutta coagulates very slowly, hence the native name "*Chayer*," which means watery, &c.

The gutta, which seems to be of good quality, is of a dirty white colour, but may be easily distinguished from *Taban Puteh* by its lower softening point, and the tree by its having small concave buttresses.

Getah Taban Simpor. Dichopsis Maingayi?

This tree may be readily distinguished from the foregoing by its large dark green leaves, and by its prominent veins at the back, which are covered by coarse, silky light-brown hairs, the back of the leaf itself being only sparingly covered by them.

The bark is about half an inch thick, rough, and of a reddish-brown colour, much covered by a greyish lichen. It has medium-sized buttresses with a concave outline.

One tree that I measured was three feet three inches in diameter, at six feet from the ground, and from that height the buttresses sloped out until they reached the ground, having a spread of about three feet from the trunk.

The flower is white, and comes out in the beginning of April or the end of March; but its fruit I have not yet seen.

I had one tree felled, which, at three from the ground, measured seventeen inches in diameter and sixty-three to the first branch. The weight of gutta obtained was 12 oz. The sap, by the aid of heat and stirring, coagulated in twenty-three hours after tapping.

This gutta is sold under the name of *Getah Puteh*. The tree grows on hills up to about the same height as *Taban Puteh*.

Getah ——. *Dichopsis* ——.

This is very much like the foregoing, but the leaves are of a lighter green, and are not so much coated with hairs; the bark is smooth.

I have not yet seen the flowers, but the fruit is green, smooth, devoid of hairs, and ripens in August. I found it growing near the *Taban Sutra*.

Its gutta is slow in coagulating and softens at a lower temperature than the lastnamed variety; and it becomes rather sticky when heated, and remains so for some time after it has cooled.

Getah ——. *Dichopsis* ——.

This tree has large, glossy, dark-green leaves, the backs of which are coated with rich warm chocolate-brown hairs, more densely on the veins than elsewhere, and the midrib is coated in a similar manner on the top surface of the leaf for about two-thirds of its length.

The bark is very rugged and greyish-brown in colour, containing so little gutta that it is not worth collecting. I have found it growing on hills about 800 feet high, but as yet have not been able to procure flowers or fruit.

Getah Taban ——. *Dichopsis* ——.

Trees of this variety are said to be growing on the Gûnong Miru range, near Kuâla Kangsa, to have small leaves and to yield gutta of good quality; but I have not yet fallen in with it, nor have I had an opportunity as yet of collecting any specimens of it.

* Chayer=liquid.

Getah Sundik. Payena Leerii.

This variety grows in swampy places near the coast, and I found one tree with its root in a small creek, the water of which was quite salt, and only a short distance from the regular Mangrove trees fringing the stream. The leaves are small, shiny, and have a reddish tint when young. The bark is about three-eighths of an inch thick and dark brown in colour moderately rough.

The flowers are white and the fruit is sweet and eaten by the Malays. Its gutta is like Taban Sutra in appearance, and is collected by scoring the bark, catching the sap, and boiling it until it coagulates. A tree measuring two feet and eight inches in circumference at three feet from the ground and 38½ feet to the first branch that I had felled gave 6½ oz. of gutta.

Getah Sundik. Payena ——.

This is a tree much resembling *Payena Leerii*, but differing from it in the leaves being longer in proportion to their breadth, the fruit and seed smaller, and the bark, which is reddish brown, is only about one-half the thickness, and consequently the yield of gutta is much less (the yield seeming to be in proportion to the thickness of the bark). This variety, therefore, is less valuable commercially than the thick-barked kinds. I may observe that it grows in swamps like the *Leerii*.

Getah Gahru? Bassia ——.

This is one of the Bassias nearly allied to *B. Mot'eyana*; and it grows on the hills up to an elevation of 2,600 feet. The bark is light grey, and the wood seems to be of good quality.

The leaves are dark green and the flowers white.

The fruit is reddish-brown, and covered with silky hairs, like that of *Dichopsis Gutta*.

The style is often persistent. Its gutta is white and hard, and is used only for mixing with better classes of gutta.

There are several other Bassias which yield gums that are used for mixing also, but I have not as yet obtained any botanical specimens of them.

Kayu Jelutong. Dyera ——.

The gum from this tree is known as *Getah Jelutong*, and is employed in the same way as that from the various kinds of Bassia.

The word "*Kayu*" means *wood*, but it is at times used by Malays instead of "*Pokok*" a tree, where they consider that it sounds better.

This tree is one of the loftiest to be found in the jungle, and has blackish-grey bark (white inside) which yields great quantities of white sap when cut into. It bears large bean-like pods in pairs.

Its leaves are green above and bluish-white beneath, and arranged in whorls at intervals, with seven leaves in each. The wood is white and very soft, and is largely used by the Chinese for making coffins, for which purpose it is well adapted, as it is light and decays very rapidly when exposed to moisture.

On the great loss of Gutta, resulting from the wasteful mode of extraction employed by the Malays.

Whilst engaged in collecting specimens and information respecting the gutta-producing trees of Perak, I was greatly struck by the exceedingly small amount yielded by even large trees by the present Malay method of ringing the bark, which led me to an examination of the dried bark with a view to ascertain, by a series of careful experiments, what proportion of the whole amount of gutta contained in a tree was actually left in the bark after the usual process of extracting it had been performed.

With this object I had on the 24th of May, 1883, a tree of *Getah Taban Simpor* felled, and scores cut in the bark at distances of fifteen inches along the whole length of the trunk, and obtained 12 oz. of gutta. Some two or three days after I had some of the bark removed, and on the 29th I cut some of it up into thin slices across the grain, and boiled them in water for a short time when I found that gutta had been expelled, and remained as a slight and irregular coating on the chips. This I picked off, and weighing it, I found the yield to be 3½ per cent of the wet bark operated on.

Encouraged by this simple and satisfactory experiment I next had a weighed sample of bark pounded in a mortar and then transferred it to a glass vessel and boiled it in water.

In a few minutes the gutta formed itself into small detached white flakes, and by stirring, collected into a mass, which was easily removed from the flask, and purified by reboiling in clean water. By this method the sample of *wet* bark yielded 5·3 per cent of clean white gutta.

Another weighed sample of bark was cut up and dried in the sun, and then put into chloroform, and after standing some hours, with frequent shakings, the liquid was poured off and allowed to evaporate, fresh chloroform being added to the bark to extract any gutta which remained in it. The total product thus obtained was 5·7 per cent of the weight of *wet* bark used in the experiment.

I next took a weighed sample of wet bark and cut it up into small chips, and dried it thoroughly, and found as the result of several experiments that it lost 50 per cent of its weight in the process.

The following deductions may be made from these results:—*Firstly*, that the wet bark which is now allowed to rot in the jungle contains fully 5·7 per cent of its weight of Gutta Percha, or when dried 11·4 per cent; and *secondly*, that by simply pounding or rasping and boiling the bark, nearly all the gutta which it contains may be extracted.

After the tree was felled I made careful measurements of it and weighed portions of the bark, so that I could calculate the total weight on the trunk of the tree up to the first branch, which I found to be 530 lb. when in the wet state.

Now if we take 5·3 per cent of this as being the amount of gutta that may be extracted by the process of pounding and boiling already specified, we find that it would yield 28 lb. over and above the 12 oz. which were obtained by the ordinary Malay method; or, to put it in another way, that for every pound of gutta collected at present, 37 lb. are wasted!

In the Kew Report for 1881 I find it stated that in the year 1875, the export of gutta from the Straits Settlements and Peninsula was estimated at ten millions of pounds weight.

I have no means of ascertaining the accuracy of that estimate, but accepting it as being tolerably correct, we must, from my experiments, come to the conclusion, that even if we take the amount of gutta wasted, at only thirty times the weight of that collected, there were, during *that one year*, no less than three hundred millions of pounds, or putting the price at only *2s. 6d.* per pound, £37,500,000 sterling worth of Gutta Percha thrown away and utterly lost!

To fully realize the importance of this subject, it must be borne in mind that this vast destruction of these valuable trees (which are of such very slow growth) and of this *material*, on which the communication of the world may be said in a measure to depend, is going on *every* year without any cessation whatever.

It will be noticed that I have left out of my calculations all the bark on the upper part of the trunk, and on the branches, which however is just as rich in gutta, as the lower portion of the trunk; even the leaves contain a notable proportion. I have tested also other varieties of these trees and have obtained almost identical results, therefore I need not enter into further details.

The question naturally arises, can the bark be broken from the trees and dealt with in the country, or can it be dried and sent to Europe, to be ground up and treated in the manner I have described, or in some other way sufficiently economical as to be commercially successful? This question deserves the most anxious attention, especially of those who are engaged in the working up of this material; for if it can be successfully accomplished, then the same supply could be furnished with *one-thirtieth* of the present annual destruction of trees!

With the object of having this point so far tested, I have collected some bark, and am sending it to the Royal Gardens at Kew, with a request to have it sent to one of the large manufacturers, so that a report may be obtained from them on the subject.

The labour involved in stripping the trees, carrying out the wet bark from the jungles (where no roads, or even paths, exist), drying it, carrying it to a port, and thence to England, are items of expense, which must not be

overlooked. At the same time, it must also be remembered, that some other jungle products, quite as bulky, and not so valuable, are yet exported with profit.

If the gutta contained in the bark can be profitably extracted, the planting of those trees on waste lands might possibly be undertaken by Government with every prospect of success.

The variety that seems to be most easily grown is *Payena Leerii* (Getah Sundik).

This tree fruits freely, and will thrive on the swampy plains near the coast; and is said by the Malays to grow fast. Its wood is hard, with a close grain, and takes a good polish, therefore may be of some value as timber.

I have tried experiments in making cuttings of some of the Dichopsis, but have not had any success as yet; although it is probable that they may be propagated by this means, when the proper mode of effecting it is found out.

I have not tried *Payena Leerii* as yet, but hope to be able to do so very shortly.

L. WRAY, Junr.

—*Journal of the Straits Branch of the Royal Asiatic Society.*

AGRICULTURAL BREVITIES.

(From the *Queenslander.*)

TWO New Yorkers, now in Florida, claim to have discovered a chemical process that will preserve oranges for a year without impairing their flavour.

A WRITER in the Adelaide *Garden and Field*, who has had forty years' experience at almond growing, says that almonds must always be grafted to insure a crop of pure soft shells.

AN American paper says:—The best labels for making plants are made from zinc, and nothing but a common lead pencil is needed to mark them. The writing is at first faint, the same as if made on glass, but soon becomes distinct when exposed to the weather.

A CORRESPONDENT of the *Auckland Weekly News* states that an infusion of blue gum leaves stands unrivalled for healing sores on the necks or breasts of horses. The same remedy taken internally is also said to be a certain cure for colds and similar complaints.

COMMON salt added to the manure heap is highly recommended, as it is not only useful as a fertiliser, but also as an agent for supplying chlorine, which is found to be an important substance in the composition of many plants, and exists in certain quantities in all of them.

A LEMON tree in Volusia County, Florida, is said to have 1,900 lemons on it.

THE VALUE OF GREEN MANURES.

Farmers (remarks the *New York Weekly Times*) have an exceedingly inadequate idea of the value of green manures. One who will sow his seed and wait patiently for the crop will be too impatient to grow a crop of rye or maize or clover to be ploughed under to enrich the soil, and return its rich harvest another year. Another will spend hundreds of dollars for purchased manure or fertilisers, but will not spend tens in growing a plot to plough into the soil for the same purpose. And there are farmers who have determined to plough under a clover sod and have top-dressed in the autumn or winter with this intention, but who have lost heart when they have seen a luxuriant growth on the ground, which seemed to be "a waste of good fodder," as they have said and so they have waited and have either pastured it or mown it off and robbed the soil of food which it sorely needed. This would seem quite different if farmers would think of their soil as something to be fed and supported to enable it to yield its produce, as much as a cow that yields milk, or a sheep that yields wool. There are some close analogies between our fields and our animals. An animal is a machine—if we like to call it so—by which we make saleable products from raw materials. It is inexhaustible for its term of life so long as it is fed; but it is really inexhaustible in fact, because, before its useful life ends, it reproduces itself several times and simply becomes a link in a chain which we may draw out indefinitely without reaching the end of it. So that in this view of it even an animal is inexhaustible so long as it is fed. And so is the soil and no longer, and, indeed, if it is not fed, a field will be more dead useless matter just as a starved cow or sheep will be. The farmer must learn to think of his land in this way or he gets a wrong idea of it. He must not neglect to study up the science of feeding his fields as he reads up that of feeding his live stock. He must become acquainted with feeding tables and rations and kinds of food for the land as well as for animals, and must provide them liberally. And as clover is accounted an excellent food for stock, so it is an excellent food for land. But, at the same time, as there are other fodders which can be used along with clover, or as a substitute when helped out by more stimulating food, so there are other crops besides clover which may be made to serve as food for the soil. Indeed, the soil is not very exacting in this respect, although it will never give something for nothing, and always returns freely in exact proportion to what it receives and no more: but it is omnivorous and has an exceedingly strong digestion. So that the farmer cannot go astray if he will always provide something for it. It may be weeds and no more, but it is better if it is a crop of buckwheat, and better still if it is rye or maize or even turnips or rape, but best of all if we can give it rich clover which goes down deeply and draws food from the subsoil and opens its broad leaves to the air and gathers from that source too, as well as others which other plants cannot reach, and so gives to the farmer a hundredfold in return for the seed and labour he has expended. There are other ways of manuring the soil, but among them ploughing in of green crops has no superior.—*Queenslander.*

NOTES ON RECENT DONATIONS TO THE MUSEUM OF THE PHARMACEUTICAL SOCIETY.

BY E. M. HOLMES, F.L.S.,

Curator of the Museum of the Pharmaceutical Society.

ESSENCE OF LIMES FROM TRINIDAD.

In March last there was offered for sale in the London market some oil of limes which differed very considerably in flavour from previous consignments. A sample of this oil, presented to the Museum by Messrs. Wright, Layman and Umney was so exceedingly fragrant and bore so strong a resemblance in colour and odour and taste to the finest or "perfumer's" essence of lemon that it was difficult to believe that it could have been obtained from limes. Under these circumstances I asked Mr. J. O. Braithwaite to compare it with other commercial samples of the oils of lemons and limes, and he reported as follows:—

At 60° F.	Essential oil of limes, Trinidad.	Essential oil of limes, commercial.	Essential oil of lemon, *a.*	Essential oil of lemon, *b.*
Sp. gr. ...	0·8741	0·8655	0·8566	0·8622
Boiling points	177·7° C.	178° C.	175·5° C.	177° C.
		Colour test.		
Nitric acid ...	Dark red-brown.	Brown.	Red brown	Yellowish brown.
Nessler ...	Canary-yellow.	Egg yellow	Canary yellow.	Pale canary-yellow.
Phosphoric acid ...	Deep umber.	Light red umber.	Umber.	Red brown

"The solubility of the Trinidad oil is very different from that of commercial essence of lemon. It is soluble in the proportion of 1 part in 5 of alcohol of sp. gr. 0·838; so is commercial oil of limes.

"Commercial oil of lemon is barely soluble in the same menstruum in the proportion of 1 in 15.

"The taste of the Trinidad oil, while quite different from that of commercial oil of limes, has a slightly peculiar but not unpleasant after-taste."

Being puzzled to know why an essential oil differing so much in flavour from ordinary oil of limes should be exported under that name, I made inquiries of Mr. H. Prestoe,

the Director of the Botanical Gardens at Trinidad, who has sent the following interesting information:—

"Your remark that the odour of the oil is rather that of lemons than of limes is quite correct. It is to be observed that the odour of West Indian limes, as produced here, is rather that of lemons, as produced in Europe than of limes produced there. The young shoots and all tender parts of the lime here have the odour of *Aloysia citriodora*,* the stronger lime odour being developed in the older parts. In the treatment of the fruit for obtaining the essence, the more rapid the process, the more pronounced is the lemon odour in the result if perfectly fresh fruits are used. The strong flavour of limes, more or less tinged with that of turpentine, seems to be a result of treating stale or decomposed fruit tissue. The plan adopted on economic grounds in Dominica and Montserrat of crushing the limes as received from day to day and then, on the attainment of a large quantity of pulp, proceeding to boil down or distil, seems completely preventive of a fine flavour in the resulting essence when obtained. I might mention also that in some of our samples the essence has been obtained from lemons mixed with the limes, the two being grown on the same field and worked off by hand together. I may add that our limes are the finest in the West Indies, and are produced on trees quite unmatched for size and exuberance in any part known to me in the Western tropics."

The mystery is thus solved. If this product can be placed on the market at a price to compete with the Sicilian article and of quality such as the sample now in the Museum of this Society, there is every probability that it will soon come into demand for purposes of perfumery and culinary flavouring, etc., for which it is peculiarly fitted by its pure fragrance and great solubility in alcohol.—*Pharmaceutical Journal.*

OIL OF LIMES.

Sir,—Since the appearance of my remarks on Trinidad Oil of Limes in this Journal, I have received a letter from the Montserrat Co., Limited, in which I am informed that the statement therein quoted by me from Mr. Prestoe's letter, to the effect that "the plan is adopted in Dominica and Montserrat of crushing the limes, and then, on the attainment of a large quantity of pulp, proceeding to boil down, or distil," is quite incorrect, at all events as respects Montserrat. The writer adds the following remarks:—"We feel sure that Mr. Prestoe made this statement in ignorance, and would be the first to wish to correct it. The whole of the Montserrat lime essence is made upon our estates, which probably turn out three times as much as all the rest of the West Indies put together. All that we manufacture at present is hand made, neither submitted to boiling or distillation, and the quality is universally admitted to be the finest in the market." I have not had the opportunity of examining a sample of the oil of limes prepared by the Montserrat Co., but of all the samples met with in commerce that I have examined, not one would bear comparison in odour with the specimen of Trinidad oil of limes of which I wrote. In fact I am told that the latter was not recognized as oil of limes by the usual buyers of the article, which is sufficient evidence for my statement that it differs from the ordinary oil of limes.

The Montserrat Company's letter indicates, however, that the difference I have observed is not due to the reason assigned by Mr. Prestoe, and that there must be some other cause for it. I should be the last to wish to publish incorrect statements, or to injure the reputation of any genuine commercial product, and should be glad, therefore, if you will afford me the opportunity of publishing the above statement. If the product of the Montserrat Company has the same fragrance as the Trinidad specimen that I examined, there can be no reason why it should not still be considered the finest in the market.—E. M. Holmes.—*Pharmaceutical Journal.*

* I had enquired in my letter whether the oil was obtained from lemons or from the lemon-scented verbena (*Aloysia citriodora*).—E. M. H.

Abrus precatorius still seems to be attracting some attention, and is to form one of the subjects for the debate on Indian drugs at the meeting of the British Medical Association at Belfast. In the *Journal de Pharmacie* (June, p. 468), M. Patein gives an account of an examination of the testa of these seeds. He finds them to contain a large proportion of carbonate of lime and rather more iron than hæmoglobin. The colouring matter is soluble in alcohol and contains, so far as has been ascertained, a salt of iron. It is thrown down completely by subacetate of lead as a greenish precipitate. It is also turned green by alkalies and is reddened again by acids.—*Pharmaceutical Journal.*

Refining of Shellac.—The crude shellac is refined in the following way:—One and a half kiloliters of soda are dissolved in forty-five liters of water contained in a small boiler or kettle; five kiloliters of the crude shellac are added in small quantities at a time. This turbid solution has the characteristic odour of shellac, and a violet-red color. The liquid is boiled for a few minutes, and, while hot, a wooden air-tight cover is cemented on the vessel. When the liquid is quite cold, the cover is removed, and the thin cake of fat which is found on the surface is separated. The solution is filtered through linen, the clear filtrate slowly decomposed with dilute sulphuric acid, and the resulting shellac washed with water until no acid reaction remains. The washed resin is now pressed, and melted in boiling water, when it can be shaped with the fingers. This shellac is cooled in water containing glycerole, and, when hard, is dried. The refined shellac forms yellowish-white glistening tufts or bars, which, when dry, are yellowish-brown; should entirely dissolve in alcohol.—*Popular Science.*

Petroleum a Wood Preserver.—Petroleum is a valuable wood preservative. Wood of white pine exposed fully to the weather and treated to a wash of petroleum sixteen years ago, says a writer in the New York *Tribune*, remains hard and sound within a sixth of an inch of the outside, or so far as the oil penetrated, brown and compact, while further in the pine has its usual white appearance. The oil with its solid ingredients in solution entered and filled the pores of the wood and changed it in both texture and appearance to something like cedar. He used it first on the roof of a dwelling and on the shingles of several barns; and after a lapse of sixteen years they appear to be as sound as when first laid. Where the roofs are much shaded no moss has formed on them. One of the barns had a steep roof, from which the oil caused the snow as soon as it accumulated in any quantity to slide freely, and this freedom from heavy loads of snow continued for several years.—*Independent Journal.*

The Nardoo.—With reference to the Nardoo (Marsilea), so common in all our swamps, I have been informed by a gentleman who was at Cooper's Creek at the time of the death of Burk and Wills, that (speaking of the aborigines) after the swamps have dried up they collect the Nardoo in large quantities by kneeling on the ground and scraping it together. It is then put into a "cogie," or piece of the sap-wood of a tree, with a hollow knot or protuberance which forms a cup-shaped cavity, where it is freed from earth or other dirt, and then ground in a quern, which is simply a flat stone slightly hollowed out in an oblong form. The process of grinding is performed with a round, smooth boulder, and is facilitated by the addition of a little water, or if that is scarce, by a squirt from the mouth, and when it is reduced to a sticky pulp it is fit for use. Contrary to the general belief, the Nardoo is never converted into bread by these blacks. In the wet season, when the Nardoo is not procurable, the blacks derive a good deal of their support from the seed of a Myrtaceoous tree, which he believes to be a species of Eucalyptus, and known there by the name of Yellow Box. When the fruit is nearly ripe a small patch is cleared round the tree and confined by branches, to prevent the fruit from escaping when thrown on the ground. When a sufficient quantity has been cut down they are allowed to remain on the ground till the capsule bursts and discharges the small seed, which is then collected into the "cogie," and afterwards manufactured like Nardoo. Also from the seeds of a tall grass (evidently a Panicum), known by the aborigines as "Pawpa," which is treated in a similar manner to the Yellow Box seeds. Hats are made from the stems of this grass simply by sewing them together.—P. A. O'Shanesy on the Flora of Queensland.—*Gardeners' Chronicle.*

THE COMMERCE OF CHINA WITH BRITAIN: ESPECIALLY ITS TEA TRADE.

In the London *Times* of August 8th, there is a very interesting and at this juncture a very important paper, one of a series, evidently, by Mr. Colquhoun on the "CONDITION OF CHINA." The year 1882 has been chosen to represent the commerce of the Empire because speculation largely upset the conditions of trade in 1883. This being kept in view we learn that in 1882 the tonnage engaged in the foreign and coasting trade was equal to 17 388,852 tons, of which

61·47 per cent was borne by English vessels, while China took 26·16, Germany 3·85, France 3·55, America 0·92, and Japan 1·81. The total value of the trade was, in round numbers:—Foreign trade, imports, £22,550,000; foreign trade exports, £19,560,000; coasting trade, inwards, £42,160,000 coasting trade, outwards, £36,100,000; total £120,370,000.

Of the percentage put down to China, England has a very large interest, the precise proportion of which is not to be determined. It may safely be asserted, however, that England, with the aid of her colonies India, Australia, Hongkong, and Singapore, and the markets of Africa and America, has absorbed four-fifths of the whole trade done by China with the foreign countries. Continental Europe takes only 8·41 and Russia 1·17 per cent. To the Anglo-Chinese trade, as thus calculated, must be added nearly all the considerable and growing trade with Indo-China—Singapore, Bangkok, Saigon, Java—which centres in Hongkong, and to this list may also be added Tonquin. The greater portion of this Indo-Chinese trade consists of the import of rice to Hongkong, and the export, in return, of industrial products from that great free entrepôt of trade. Unfortunately no figures are available to indicate the volume of this commerce, nor, of course, to show the amount of the fraudulent junk traffic along the coast which, however, is known to be considerable.

There are figures then given to show the changes since 1851, when the balance of trade between China and Great Britain was £2 000,000 against China. In 1854, the imports of British goods were to the value of £6,000,000, the figures for 1882 being £21,000,000, an increase of 3½-fold. The value of opium sent to China had gone up from 15½ millions of taels in 1854 to 26,746,297 in 1882. Cotton, woollen and other piece goods were valued in 1882 at about a million taels in excess of this amount, metals 4,700,533 taels and sundries 18,773,466 taels, while in 1854 the figures for cotton goods were only 2,609,000 taels and all other articles (except opium) 3,640,000 taels. In exports from China to Britain the value has risen from £4,681,043 to £19 084,439. The leading article, tea, increased in value (quantity being much greater in proportion) from 9,700,000 taels in 1854 to 31,332,207 in 1882: that is from £3,258 593 to £10,525 593 15 0. Silk rose from a value of 5 350,000 taels to 22,837,252; sugar from blank to 3,103,010; and sundries from 975,000 taels to 10,064,010. The increase in the total trade between the two countries has been from £10,681,000 in 1854 to £40,084,000, or nearly 4-fold. But Mr. Colquhoun says that the total for 1882 is the lowest since 1878, when the figures for aggregate imports and exports were £39,100,000. It is added:—

In imports there has of late years been a remarkable decrease in Indian opium, the deficit for the year 1881-2 amounting to nearly £2,000,000 for Malwa, and £850,000 for Bengal, opium, in all, £2,850,000. Cottons and woolens showed a decrease of £1,500,000. In opium and piece goods alone, therefore, there was a decrease of over 4½ millions. The year to piece goods importers was the most unsatisfactory since 1877. The reasons assigned, all reasonable, were the less prosperous condition of the country people, the droughts in Shansi and Mongolia, the floods in Shantung and along the Yangtse, and the small sugar and rice crops in the south. The most powerful reason, however, probably was that the year was everywhere a bad year for tea and silk. Consequently China, the producer, was not able to invest so freely as usual. The sale of piece goods has not increased largely, and will not increase, until the cost of production is reduced to a point within the purchasing power of the consumer. The factors in the question are the yield of the cotton crop and the cost of labour in the United States and England. Mr. Drew, the able statistical secretary to the Customs, asserts that in the wake of a superabundant harvest of cotton will surely follow a large influx of cotton goods into China. It is no question of American *versus* English makes, not of sizing or not sizing—for Chinamen have reasons for buying both—it is merely a question of bringing the cost within the limits of the Chinaman's purse. The reason for the steady decrease in the opium import, most marked in the north, is without doubt mainly due to the increased area of poppy cultivation in China, and the improved quality of the drug. Into this question I shall, however, examine at greater length later on.

In exports the value of silk decreased over £1,000,000, though the quantity remained the same. Tea is steadily falling off, showing a decrease for the year of nearly half-a-million. Thus silk and tea account for a deficit of over £1,500,000.

And then comes the portion most interesting to tea planters in Ceylon and India:—

The decrease in tea is in small part due to certain alterations in the conduct of the United States trade, whereby the green teas are now "rushed off" by auction to the lowest bidder. The trade has thus become concentrated in the hands of a few houses, who having large capital work on very low profits, or solely on commission. But the supreme reason is competition, as regards green tea from Japan and black tea from Assam. At Foochow I found that tea, for which the grower receives only 1d per pound, costs over 1s when delivered in London. Of this 2¾d goes in China for duties and 6d in England. The tea export will certainly decrease until free transit and European methods of cultivation and curing are introduced. Without such reforms the Japan and Assam teas will annually drive the China article more and more from the foreign market.

Much might be written on the subject of the tea trade, but space forbids. A few particulars, not usually known, must be mentioned, however. In the trade it is roughly divided into black, green, and brick tea. The first two go to Europe and America, the brick tea being sent by Russian merchants established in China to Mongolia, Manchuria, and Siberia. The natural tea, the most delicate and best perfumed, made with the leaves of the extremities of the branches plucked before the first rains, known under the name of *yu-toyenn*, is kept by the Chinese for themselves. Highly esteemed by the richer classes, it sells at heavy prices. The so-called "Puerk," known also in China as Yünnan tea, but which comes from the Shan States south of Yünnan, is highly prized for its pharmaceutical qualities, being reputedly a certain cure for spleen, bile, and hæmorrhoids. One fact regarding tea may astonish many people not a little, not only in England but in China. Its use among the 300,000,000 of Chinese is by no means so common as supposed. As a fact, the poorest classes in Shansi, Honan, Shantung, Yünnan, and Kwang-si, know it only as a luxury. The peasantry of these provinces, especially the north, sip hot water with the same relish as a Fokien man taking his infusion of Bohea, and try to cheat themselves by giving the innocent beverage the name of tea. In south-western China I found hot water thus used, and have drunk it myself in Western Yünnan.

It will thus be seen that the competition of Japan, to some extent, but far more that of Assam—that is of Indian teas—is telling very seriously on the great (although grossly exaggerated) tea produce of China. We need scarcely tell our readers that India (and Ceylon) tea is destined still more to compete with and supersede the Oolongs of Japan as well as the

black teas of China. We cannot help sympathizing with the poverty-stricken peasant producers of tea in China, but the inevitable cannot be helped. It is not in war alone but in the arts and products of peaceful industry that the Western nations are so unquestionably superior to the inhabitants of the Far East. European planters cannot certainly compete in cheapness of production with the Chinese, if it be true, as stated by Mr. Colquhoun, that for a tea which sells for 1s per lb. in London the producer receives only one penny! We have read of the frugality of the Chinese and of the smallness of the number of "cash" for which in ordinary times a meal can be purchased, but, with all that, it is utterly impossible that a penny for a pound of made-tea can nearly repay the labour of the producer. But let our readers just look at the fact, that on this product, for which the man who has toiled in growing, and partially at least preparing it, is paid one penny a pound, is taxed very nearly 75 per cent of the selling price in the shape of duty by the Governments of China and Britain. For the tea-growers of China are placed at the serious disadvantage by their own Government that their produce pays an export duty of 2¾d per lb., an addition of 6d in the shape of import duty being levied on it by the British Government ere it can go into consumption. The producer pocketing his wretched penny and the Governments of China and Britain making a levy of 8¾d, there remains the magnificent sum of 3¼d to supply profits to purchasing merchants in China and brokers and wholesale and retail dealers in London! But surely Mr. Colquhoun is mistaken in supposing that even the lowest quality of China tea, which has paid 2¾d duty on export from China and 6d import duty in England, can be sold, even wholesale, for one shilling per lb.? One thing is certain: that, as stated by a writer from Foochow, quoted in our columns today, the position of the China tea trade is wretched. Had the country a Government worthy of the name, the export duty of nearly 3d per lb. would have been remitted as soon as it became evident that Indian tea had broken down the long-standing tea monopoly of China, and was not only competing with but rapidly distancing the best orange pekoes of "the flowery land." The action of China gives the Indian planters an advantage of 2¾d per lb. over their Chinese competitors, apart from the presence of labour-saving machinery and the absence of those unauthorized but no less onerous "squeezes" to which the poor Chinese peasant tea-grower is subjected. In India there are no export duties, and, deficient as means of communication still are in some of the remote districts of Assam, the lot of the Indian tea planter is immensely better than that of his Mongolian competitor. In Ceylon there is a trifling export duty levied on tea, but it is for a specific object and in lieu of a tax which was previously levied on acreage. Here, on the other hand, there is an import duty of 6d per pound on tea, which, now that our export of the article has reached 2,000,000 lb. in a year, has assumed the aspect of a protective tax, which will, doubtless, be removed, as we feel it ought to be, at the approaching revision of our tariff. The quality of Ceylon tea is too high to require any bolstering-up of this sort. Our fellow-subjects in India as well as the Chinese will have reason to complain if the Ceylon duty of 6d per lb. is retained. The sacrifice of revenue will be but trifling, as the duties collected on imported tea have fallen off greatly and are diminishing year by year. We have now the evidence of Mr. Colquhoun against what we always felt were the grossly-exaggerated estimates of the amount of tea grown in China, calculated on the supposition, contrary to fact, that tea was in universal use as a beverage by the three hundred millions of China. As a great many natives of India and Ceylon seldom eat rice, but have to content themselves with millets and roots, so there are millions upon millions in China who never drink anything more nearly resembling tea than hot water. The terrible poverty of the masses cannot be more vividly represented than by the fact that they cannot afford to use at home a product for which, in order to be exported, the producer consents to receive only *one penny per pound*. On every possible ground, we have reason to hope that the war now waging, however disastrous in its immediate results, may tend, with other causes, to such changes in the Government of China as shall vastly improve the condition of the masses of this industrious but down-trodden and now for ages unprogressive people. With railways and roads radiating over her surface, China would be amongst the wealthiest and happiest, instead of one of the poorest and most wretched of nations.

Having thus fully discussed the subject in which we in Ceylon are chiefly interested, we may add, that according to Mr. Colquhoun,

The decrease in silk is owing mainly to competition from Japan, where crops have lately been excellent, and partly to disease in the silk-worm. The trade for some time was upset by the operations of a Chinese banker in Shanghai, who kept buying constantly and maintaining high prices, notwithstanding the depressed state of the London and Lyons markets. The total held by this operator at one time was 14,000 out of a total of 18,000 bales, the usual stock being five to 6,000 bales. The venture collapsed, and the market has again resumed its normal condition. The silk producing power of China is enormous. In 1843 not a bale left China, in 1845 over 10,000, in 1855 over 50,000 and in late years between 50, and 100,000 have been exported.

In 1863 nearly the whole was shipped to London even the Lyonese industry being in the hands of English agents. Now the French silk industrial centre receives more than double the amount shipped to London, and the work is carried on by French firms. So greatly have the French attracted the trade, that the P. & O Company has, within the last year, been compelled to resume its line from China to Marseilles. Filature factories in China have been started for the most part with Chinese capital under English or American management. For these, skilled workmen from the valley of the Rhine, the home of the silk industry, have been brought out. The attempt has not hitherto succeeded, but serious competition will yet arise and deserves the attention of the home industries. From Shanghai is exported four-fifths of the amount annually exported from China, the balance coming from Canton. But Southern China is a sealed letter, not only as regards silk, but trade generally. Both in the southern provinces, and in Tonquin when opened up, a considerable silk industry may be confidently expected.

And then as to the trade with Britain:—

The average balance of trade, which from time to time varies greatly, was, for the four years previous to 1882, £2,750,000. While the imports have increased 350 per cent. and the exports 400, since 1854, the ratio of the balance of trade in 1882 has increased only some 40 per cent. The progress made since 1860, the time of the last European-Chinese war, is by no means commensurate with the expectations which were reasonably entertained, and it is noticeable that the foreign trade has been at a stand-still during the last dozen years.

The most marked feature, and the one which concerns us most—for it involves the loss of an income of £6,000,000 sterling to England—is the decrease in the import of Indian opium. There cannot be any doubt but that the foreign drug will be driven, slowly perhaps, but steadily, by native competition, from the China market.

Mr. Colquhoun then goes on to show, what other writers have proved over and over again, that the Chinese Government is anything but sincere in its professed desire to put down the use of opium altogether. On the contrary, the internal growth of poppies has been encouraged. Mr. Colquhoun does not see how

opium eating can be or ought to be put down by force, any more than alcohol-drinking. Opium is the Chinaman's, or rather the Mohamman's, substitute for spirituous stimulants. Both do terrible harm when taken to excess, and, in the cases of particular constitutions, but for the disuse of or repression of excess in each, we cannot trust to Government action. To quote again :—

The Chinaman, like men of other races, insists upon indulging in some stimulant or narcotic, and he has choosen opium. He is by no means the teetotaller which he is credited to be. Temperance societies exist in China. Still the Chinaman generally does not indulge in beer or wine—a great debarrent being the cost when delivered from Europe—and his *samshu* is a weakly subterfuge. The vice which it pleases him to indulge in is, therefore, opium. We have not yet succeeded in introducing temperance, far less abstinence, into England. And you may as soon expect the average Briton to give up his beer or spirits as the Chinaman his pipe In neither case can you make man moral by Act of Parliament. No reform, I feel certain, is likely to come from the mandarinate, who are nearly without exception slaves to the habit, while the few free from it are powerless against it. It must come, if ever it does, by social reform, from the people themselves. The import of Indian opium by our Government is said by the missionaries to create a source of considerable difficulty in their relations with the Chinese. If not altogether a sincere belief with Chinamen, it is at least a highly convenient argument, and much used by them, that we are largely responsible for the prevalence of the habit; and not only the officials and *literati*, but not a few foreigners even, have done their best to foster the idea. True or not true, the charge is one difficult to meet so long as Government preserves its present attitude with regard to Indian opium. Having in view the facts brought forward in this letter—though of opinion that the suppression of the Indian opium traffic will not stop nor even diminish its use—I think Government should take steps to discontinue it, and replace it by some other means of revenue. It can hardly be called a creditable source of revenue. From the practical financial as apart from the moral or sentimental aspect, it is advisable to examine the question and seek some means of replacing it. If no such steps be taken, Government will have lost the opportunity of carrying a measure of progress—an act of self-respect as well as expediency—for the import of Indian opium into China is doomed.

With the opium revenue failing and threatened with extinction, the imports of piece goods in a most unsatisfactory state, tea and silk decreasing each year in value, and a balance of trade close on £3,000,000, surely there is reason to consider well the conditions of our trade with China.

Yes: and we have no doubt, that, amongst other matters, the disturbance and perhaps temporary ruin of commerce which is still so vast, by the warlike action of France, will be properly considered and represented. As for the opium trade, we need not say how little we should regret it, were the Chinese, in lieu of the drug, to resort more largely to their own harmless and beneficial stimulant (tea) and to quinine as a remedy against swamp agues and debility. Deplorable as the condition of the millions of China now is, we cannot but believe that for them there is a great and bright future, to hasten which even the wickednesses and the horrors of war can be made subservient by the Greater Ruler who educes good out of evil.

NATIVE AGRICULTURE.

We had the pleasure yesterday of witnessing, and taking part in, some experiments with light English ploughs.

From yesterday's interesting experiments the Swedish plough was absent, but there were several light English ploughs of similar construction, from Howard Brothers of Bedford, imported by Messrs. W. H. Davies & Co., which they are able to supply, if a large order is secured for them, at prices ranging from R12 to R18 each, according to weight and construction. The scene of yesterday's experiment was Andanduwana, a village about 8 or 9 miles from Negombo on the old Chilaw road.

The experiments commenced about 9 o'clock and lasted over an hour—two of Howard Bros.' small, iron, single-handle ploughs with wooden pole attached taking one large bed, and four of the country ploughs an adjoining, but easier, because less clayey bed, of a large range of fields, on which no water was visible, save a small puddle in which the buffaloes refreshed themselves after their exertion. About a hundred people of the cultivator and trader classes, and some well to do proprietors, Sinhalese and Tamil, watched the experiments, and, following the ploughs, were able to see that, while the English ploughs completely turned over the soil, about 10 inches broad and 5 to 7 inches deep, the native ploughs only left a furrow 2 or three inches wide and 2 to 3 inches deep. The spaces between the furrows were untouched by the latter, while the former, although worked along only one-fourth the number of lines, turned up or loosened the whole soil.

Some of those present evidently thought it was their duty to be in opposition, and did not see the good of any change; they were content with their old ploughs; their fields yielded them enough for their wants; the new ploughs cut too deep and would give their buffaloes trouble; they were too poor to buy new ploughs, and so forth. Their objections were met good-humouredly one by one, and the advantages pressed on them of increasing the yield of their fields, of giving the paddy plant more soil to feed on, of reaching the roots of the grass so that when exposed and submerged they might rot and make manure, instead of choking the corn by their vigorous growth of association and co-operation in the use of ploughs and cattle. We were very far from sanguine of any good the ploughing match had done in overcoming ignorance and prejudice; but we were agreeably surprized in a few minutes. The opposition speakers evidently only represented themselves; those who were silent had not been unobservant of the fairness of the experiment and of the controversy, for the headmen were specially asked to take no part in it lest their acquiescence might be thought to have been purchased by official pressure. Applications were registered for no less than 14 ploughs—a good morning's work, we should say. Although it is of the greatest importance that Village Councils should be encouraged to buy ploughs, and hire or lend them to the people, the example of private proprietors, who after having paid for the ploughs are sure to use them, is likely to be more effectual in overcoming the prejudices of their neighbours, while the results in better crops will, we hope, lead to the extensive adoption of these ploughs. They are adapted not only for paddy, but for coconut land as well, and Mr. Gabriel Croos of Negombo, with characteristic energy, is setting an excellent example in using them on his estates.—"Examiner."

CEYLON PLANTING NEWS.

2nd Sept. 1884.

The change of weather deserves a word. How grateful the rain is, and how welcome! Still the monsoon is keeping up its mild character; no need to knock off work in our part of the country, such a thing as wash unknowo, and the coolies agitating only in a mild way for new cumblies. Everything is looking refreshed, and the promise and bud of renewed life is manifest in every bush and tree. One peculiarity of the long drought which I noticed was the frequent visits from troops of monkeys. I have not seen them hereabouts for many years, but lately, when the weather was dry and a little red coffee about, we have had them by the fifties, doing their best to reduce the large European stocks of coffee, and alas! also our profits. It is bad enough to see the ground littered thick with dead leaves brought down by the fungus; but the addition o colour, although desirable enough in an artistic point of view, does not commend itself to the planter, when the dash of brightness is obtained in the form of empty skins of the ripe berry.

I see that there is an anticipation of a large proportion of light coffee this year, and very likely it may turn out to be so, but the results of a few small pulpings which I have seen do not tend yet to establish that opinion. There was not more light than the average of a usual season, and I was equally surprized to note that for an early picking the sample was good. The dying-back of branches, and as a consequence the blackening of the coffee at the points, is very excessive, and you don't know what to do with it. To let it "slide" is the first idea which occurs to you, for there is little, little in the husk. But to do so would be a constant worry all through crop, and be an encouragement to the slovenly picker to neglect what of good might fall. So it is brought in, and its presence in the store is ever a mental stimulus to solve the problems who will buy it and will the price got for it pay the cost even of picking?

I had an amusing letter the other day from a native conductor of mine, and mention it now, not that it is an uncommon thing to find unconscious humour in the epistles of this class, but rather to show how near the end of the world must be when knowledge—scientific knowledge—is increasing at such a rate that its learned nomenclature actually wells up through a stratum of very indifferent nglish. When I give the extract, my readers will see that the writer has no ambition to be rhetorical, that deadliest pitfall in the way of the English-speaking native. He does not write like the Aryan brother, who, desirous of giving an idea of the April heat of Colombo, said: "The maritime capital is at present so hot, that even if I were plunged into a river of ice I could not be cool": nor the necessituous individual whose humble petition had it that he was so poor that "he had no place *into* which he could lay his head"! No, nothing of the kind; this is what he says:—"I beg to say I have taken great pains to bring up the casuarina plants, and succeeded with few hundred plants. After I have done planting, there is a loss therein in those days. Eaten away one by one by something, it is supposed by rough lizards (*Lacerta cristala*) Now I am obliged to tie a piece of paper, fix it in a stick to fly for the wind, which is considered as a scare-crow." The scientific name given above of this enemy of the casuarina—whose life-history after the fashion of these days, I purpose asking my conductor to work out—may or may not be correct, I decline to enter into the question This, however, I may say, that "the rough lizard," when it was brought in this shape to my notice, was not only rough in itself and on the casuarinas, but positively "rough" upon me. It reminded me, however, of a reply another planter got which was as staggering and quite as scientific. Some Java Ledger seed he had came up—uncommonly unlike the true Ledger—and he asked his Sinhalese conductor, who prided himself on his knowledge of cinchona, if the young plants were not the true type. "Not exactly," was the answer, after a little examination; "but they are number forty-two of the same variety"! George Eliot has it that "comprehensive talkers are apt to be tiresome when we are not athirst for information, but, to be quite fair, we must admit that superior reticence is a good deal due to the lack of matter." The employer of this Sinhalese botanically-inclined conductor had in the reply he got been somewhat "taken to the fair," and covered his discomfiture by going in for 'the superior reticence" referred to above. Need I add that in regard to "the rough lizard"—*Lacerta cristala*—I am following suit.

I have been interested for some time back in observing several cacao trees which eight or ten months ago were gnawed round the stem in a distressing manner by an unfriendly porcupine. This brute seemed not only to have torn off what bark it could in broad stripes, to have broken branches and eaten the pods, but had used the stem of the tree in the same manner in which a dog uses a bone, when it is too strong for his teeth to break: the marks of the gnawing were deep into the woody pith of the stem, and altogether it was a sad sight. The result of this barbarous treatment was to throw the tree very much back; albeit in the matter of blossom, when the due time came, it was a sight to see such a show as that with which they decked themselves. Up to the very tips of the branches the little sprig was out in such masses, as I have never seen at all approached by any of the numerous varieties of the cacao family. Of course that clustered magnificence of blossom came to nothing in the way of fruit, and it was a question with me whether it would not be well to accept what seemed to be inevitable, cut down at once the maimed trees, replant, and so save time in the long run. But I elected otherwise. The seemingly slowly dying trees were left to struggle, successfully turning the corner—after a hard fight—in all cases save two, and now they have picked up again. The bark has been steadily renewing, and they look on the whole almost as well as other trees near which had no porcupine to cheek them.

On the renewed bark I have for a few weeks now looked in vain for flowers. I knew it was said to be a peculiarity of the cacao, that bark once injured lost the power of blossoming, and, so far as my observation has yet gone, this fact seems to be established. There is no lack of blossom in the branches and the scraps of original stem bark which remain; but in the large patches of renewed, none whatever.

Pepper Corn

QUESTIONS ON THE PROSPECTS OF THE PLANTING ENTERPRIZE.

The following has reached us from the Nilgiris:—

To the Editor of the "Tropical Agriculturist."

The Neilgherry Hills, 29th August 1884.

Sir,—In these gloomy, depressing times for coffee planters, the faintest gleam of light, indicating brighter days, is not to be despised, and therefore the following extract should not be without interest.

A correspondent writes to the *Church of England Temperance Chronicle*:—"I was going North last Monday by the train which leaves King's Cross at 5-15 a.m., when I heard the following (to me) new complaint. About 7 the train stopped at a large station; a man got out of the third-class carriage I was in and went for a drink, but came back complaining that the attendant was so busy serving coffee, that she had no time to give him beer." Taken in connection with the fact that extended consumption amongst the public in general is the great desideratum, the above incident is hopeful. In order to make the English public acquainted with the great superiority of a genuine decently-made cup of tea or coffee, would it not be worth the while of planters to secure the services of a smart man of tact and experience to make a tour of all the principal coffee houses and temperance hotels throughout England, introducing Indian and Ceylon teas and coffees to the notice of proprietors and managers, and, above all, showing how a decent cup of tea or coffee should be made. The experience acquired at "The Healtheries" shows pretty clearly, I think, that the main obstacle to the more widely extended consumption of tea, especially in England, exists in the generally prevailing ignorance of the British public regarding the mysteries of the "brew." By the usual "stewing" process doubtless a stronger dose of tannin is swallowed than is quite agreeable!

Mr. Armstrong affirms that heavy or continuous rains at high elevations check the flushes of tea! Is it the rain or the terrific winds (which always accompany monsoon rains at high elevations) that is detrimental? During the abnormal weather of July when we had the monsoon wind blowing without any rain, my tea trees hardened and refused to flush as usual in monsoon weather, although the ground

was well-moistened by previous showers. On the other hand a low-lying piece of ground sheltered from the monsoon quarter by a ridge and belt of trees, flourished most luxuriantly—no hardening of leaf or stoppage of flushes—however the wind might roar or the rain prevail.

Can Mr. Armstrong please explain how it is that cinchona nurseries require more close and continued protection from the sun at high elevations than at lower? This is a well-known fact on these hills. At the elevation of about 3,000 feet I had always been accustomed (in common with my brother planters) to gradually remove the shade from my cinchona nurseries towards the end of May or early in June, just after the first showers, in order to harden the plants. I tried the same thing at the elevation of 6,000 feet with the result that all the plants so exposed were burnt up by the sun in a few days! In view of this difficulty, a planter on these hills at a similar elevation has found it worth his while to rent a piece of land in the lowcountry at 3,000 feet solely for the purpose of propagating his cinchona nurseries.

Is it that, owing to the rarified atmosphere, evaporation goes on with greater rapidity at high elevations?

How is this Chinese-Franco war likely to affect the tea market?—Yours faithfully, NOVICE.

There can be little doubt that the tendency in Britain is to the supercession of alcholic stimulants in favour of such beverages as cheer but do not inebriate; but tea seems the favourite with our countrymen and countrywomen. But, as our correspondent points out, tea is often as badly brewed in England as is coffee. Tea, however, is generally pure.

Strong wind and heavy rain generally come together and both or either must check flushing.

As regards the cinchona nurseries, we should rather suspect mischief from cold the consequence of radiation of heat into space than the scorching heat of the sun. We had experience of a tea nursery at 6,000 feet in which all the plants blackened and seemed dead, but they grew up again all right. But tea-seedlings are much more robust than those of cinchona.

AGRICULTURE IN THE NORTHERN TERRITORY OF SOUTH AUSTRALIA.

The present condition of agriculture in the Northern territory* is very disappointing, and much to be deplored. It is difficult, indeed to convey to those who are unacquainted with the facts connected with this industry during the past four or five years any intelligible reasons which account for the barreness of results. But to those who are on the spot, and who have visited the sites of the reckless or inadequate experiments which have been made, it is clear enough that avoidable blunders explains the disappointments and failures. In the one instance in which a genuine attempt has been made to establish a sugar plantation, where it is stated £20,000 have been spent in machinery, buildings, clearing, and the cultivation and planting of 182 acres, the result of the crushing of the cane of last year's growth amounted to only seven tons of sugar. The quantity of sugar which results from the crushing of the crop this year is about five tons. I refer, of course, to the Delissaville estate, and I give the naked facts, because the costly and absurd disaster there has done more to retard tropical agriculture in the Northern territory than all other causes combined; and because, unless a clear and authoritative explanation is made public, the collapse of Delissaville will scare capital and enterprize away from the Northern Territory as a possible sugar-producing country altogether. It is a source of deep regret to me in an official communication to write anything that may injure the financial prospects of a private Company, the shareholders of which have liberally furnished the capital asked for, have pluckily stuck to their venture, and certainly deserve to have succeeded. I feel, however, that this is a case in which public duty rises paramount to all private considerations; and I fear the result of this year's crushing, when made known, will have precipitated any damaging results that might otherwise arise from the publication of my report. The cardinal—the one all-sufficient—fact which accounts for the ridiculous result of five tons of sugar this year from an estate of 10,000 acres and the expenditure of £20,000 is that the land, except a patch here and there, is entirely unsuited for the growth of sugarcane. When I, in company with the Parliamentary party visited the place in March, 1882, it was the wet season. All the uncultivated portion was covered with the tall luxuriant grasses, which grew everywhere from six to twice six feet in height; and the cultivated portion, though ominously showing large quantities of ironstone gravel, appeared to have a rich, dark soil. Since then I have seen the sugar lands in the Mackay District of Queensland, and a few days ago I visited Delissaville again. Now, although I have no practical knowledge of sugar cultivation, I am not surprized that Delissaville is a failure. The Mackay sugar lands, whether plain, forest, or scrub (*i.e.*, jungle) are rich deep loam. At Delissaville the ironstone rocks crop out to the surface, and the stunted cane is fully accounted for by the poor, ironstone, and gravelly ground in which it grows. At the time of my visit last week I was accompanied by a gentleman largely interested in a sugar plantation in Fiji. He remarked that there was no necessity to talk about white ants, because the soil, or rather the absence of soil, sufficiently revealed why there was such a miserable crop. To conclude, therefore, that the Northern Territory is unsuited for the growth of sugarcane because of the failure at Delissaville is as illogical as if because a farmer tried to grow wheat in the Ninety-mile Desert and failed therefore the whole of South Australia was to be declared unfit for wheat. It is because the Delissaville Estate and surrounding land has been described "as a vast and rich sugar country" by Mr. Thompson, of Antigua, that it is necessary to show that it is the unsuitableness of the land itself which accounts for the failure. Two other attempts have been made—one on the Daly River by Mr. Owston, the other on the Adelaide River by Mr. Sergison. In both instances the land was judiciously selected, and is undoubtedly capable of producing fine crops of cane. But after the preliminary expenditure on a nursery, in each case the places were abandoned. I shall refer presently to both these places, and need only say now that the few thousands spent on them were wasted; but if planting had been continued and machinery erected, in the opinion of those well fitted to express it, there would now be prosperous plantations on each river. Sugarcane is a fairly successful crop this year again in the Experimental Garden at Fannie Bay, where the soil is plentifully mixed with ironstone. I saw also last week, at Messrs. Cloppenburg and Erickson's selection at West Point, a fine patch of rattoons. A fire swept across the plants last year, and they have been allowed to take their chance since, without weeding or care; and in the opinion of the gentleman who accompanied me to Delissaville, they are sufficient evidence that in suitable soil sugarcane will do well, even in a season like the present one, in which the rains ceased at the end of March. At Mr. Brandt's plantation, at Shoal Bay, about twenty acres of very fine cane have been grown. The cultivation there was only commenced last year, and I have now, outside my office, a bundle of cane of three varieties, some of which measure six inches in circumference, and are nine feet in height. This cane was only planted at the end of last November. Mr. Brandt is so satisfied with his selection that he will plant about one hundred acres this year, and intends erecting a small mill to crush next year. This gentleman is returning to Adelaide by the Laju, and will take a sample of his crop with him. Messrs. Harris and Head, of West Point, have also decided to make arrangements for the erection of a small mill. These familiar names represent all the attempts that are being made to cultivate cane for the manufacture of sugar. It must be confessed that the results furnish but a sorry record after the glowing reports, promises and anticipations. It is easily explained, however. The small cultivators at West Point, who have grown good cane have not had sufficient capital to erect milling machinery; and at Delissaville, where machinery has been provided, the land is too poor to grow good cane. Nor is it difficult to explain why large sugar-growers in other places have not embarked in the enterprise in the Northern Territory: 1. They have waited for the results of Delissaville. 2. They have been frightened by stories of

* Of South Australia.—ED.

the destructiveness of white ants. 3. They have fears that the rainfall, though sufficient in quantity, falls within too short a time. 4. Having been informed that Delissaville was some of the best land in the Territory, and finding that the crop was a failure there every year, they have naturally concluded that there is no land which can be depended upon to grow sugar at a profit. I will take these four points *seriatim*: 1. I have accounted for the failure at Delissaville; it is not white ants, nor insufficient rainfall, but a bad selection of barren land. 2. The white ants have never damaged the cane at the Government gardens, at Messrs. Cloppenburg and Erickson's, at Messrs. Harris & Head's, at Mr. Brandt's at Mr. Owston's on the Daly; or at Mr. Sergison's on the Adelaide. 3. The crop of cane at the gardens and at the three first-mentioned places this year demonstrates that even in a dry year like the present, sugarcane will thrive and mature to the extent of a thoroughly remunerative crop. 4. That there are large areas of land suited and available for sugar-growing on a large scale I will now show. On my arrival in Palmerston, and learning the actual position of agricultural operations, I felt it was my first duty to ascertain, by actual examination, whether or not the land on the banks of the Adelaide and other rivers is suitable for the growth of sugar and other tropical and sub-tropical plants. In Palmerston itself conflicting rumours were current, and in order that the Government might have the information necessary to determine their policy, I arranged with Mr. Holtze, the Government Gardener: Mr. Biddles, the Manager of Delissaville; and Mr. Brandt the proprietor of the plantation at Shoal Bay to accompany me on a tour of inspection. I have already forwarded a full account of the expedition, and also the reports of the gentlemen mentioned, and I respectfully recommend that their reports should be printed as an appendix to this report. [They appear in this connection.] The rough sketch plan which accompanies Mr. Holtze's report shows the points at which we landed. In each case we took with us a pick and spade and dug through the soil and deep into the subsoil. We walked over many miles and dug holes at irregular intervals, and where there were different surface appearances. The top soil is dark, and plentifully bearing roots and vegetable matter. The subsoil is a heavy bluish clay or marl, which has also a considerable quantity of vegetable fibres. The natural vegetation is chiefly the "bladey" grass. The plains are of great extent, and give ample room for a large number of plantations. The ground would require deep ploughing and through breaking up and working, for which steam-ploughs would probably be the most economical, as there is no timber to clear. Experience has proved that the heavy clay after being exposed to the air, sun, and rain, becomes friable. At Manton's Hills, where Mr. Sergison had planted, the canes, though almost smothered with grass, were still growing, and so were the bananas and pineapples. At Beatrice Hills Messrs Fisher & Lyons have planted about 7,000 coffee plants, the whole of which were in vigorous condition. They had been brought by blacks from Poett's Rum Jungle Nursery, and were out of the ground for four days. There have been only about 2 per cent of misses. There has been no rain since March and no artificial watering. I forward by the same steamer two of the plants indiscriminately selected. Beatrice Hills are very stony, and there is a large quantity of similar country in the Territory. Ten acres of indiarubber-trees have also been planted, which are doing well. The verdict of the whole party is that there is a large area of fine agricultural land on the Adelaide River. On our return we called at Escape Cliff. Nothing remains there but the brick floor of a verandah, a well, some iron tanks, a heap of bombshells, and a few poles driven in the sea at the foot of the cliff. I may add that the Adelaide is a deep-water tidal river, navigable for seventy miles, and the blacks are harmless.

Having found the Adelaide so much better than was anticipated, I thought it well to visit to Daly River, which lies about 100 miles to the westward. The "Palmerston" steamed to the mouth, and we ascended in the launch about sixty-five miles. At the place where Mr. Owston planted, the sugarcane crop had been destroyed by fire; but the charred cane showed that it had thriven well, and the young cane was again sprouting. Here, too, the bananas, pappias, and pinnapples were in full growth. In our examination of the soil we adopted the same plan of digging down through the soil into the subsoil. We found wide and deep plains covered with "blady" grass, with patches of jungle, with rich loamy soil and subsoil. The experts of our party pronounced the land to be superior to that on the Adelaide, and adapted specially for sugar where richest, for indigo where sand shows, and for rice on the plains towards the sea. The banks of the upper river are high, covered with thick jungle; but those of the lower river are mostly bare, and constantly washing away with the flood waters of the wet seasons. The Daly is more difficult to navigate than the Adelaide. The report of Mr. Holtze, with which Mr. Biddles concurred, would give, if printed, some valuable and reliable information of the Daly River, which I feel satisfied will shortly be the scene of extensive agricultural operations. The blacks, though less familiar with Europeans than on the Adelaide, were friendly. We landed among about 150 of them, visited their camps, gave them tobacco and flour, and parted from them with expressions of goodwill. The promising character of the lands on these rivers gives reason to expect that similar conditions exist on the Victoria, the East and West Alligators, the Hutchinson, the Goyder, and other rivers which flow into the Arafura Sea. This will be ascertained by the trip of exploration on which the Palmerston will shortly proceed. If the results accord with the anticipations, which may reasonably be entertained the Indian Immigration Bill will soon be in operation, and the Northern Territory, with its virgin soil and freedom from the labour difficulties and locusts of Queensland, will take a foremost place as a sugar-producing country.—*S. A. Register.*

PEARLSHELL FISHING.

The rush of a small fleet of pearling boats to Port Darwin Harbour has not resulted in a large export of pearlshell. It is, indeed, useless to ignore the fact that up to the present the results have been disappointing. About fifteen tons of pearlshell have been shipped during the quarter, the declared value of which is £2,032. The two complaints made by the pearlers is that the shell is in too deep water, and that the water is too muddy for the divers to be able to see. There is, no doubt, some force in both allegations. The divers have been working in from ten to twenty fathoms but very little in the latter depth. Diving apparatus is now made which enables a man to work freely at thirty-five fathoms; and the Manager of the Queensland Pearl-shelling Company informs me that his Company, notwithstanding the reported ill-success of the Thursday Island pearlers, have determined to bring round some boats provided with the deep-diving apparatus, and thoroughly test the harbour and the coast. One reason which accounts for poor getting is that the majority of the divers which have come here have been indulging in a prolonged debauch, and have been, of course, unfitted for their work. I was informed by a gentleman, who learnt the particulars from one of the crew, that their boat was outside for some time, and when they came back they all said "no luck, no findee shell." But the fact was one diver had only been down three times, and that but for a few minutes. The best proof of the confidence entertained is that the local Companies will carry on their operations, and a boat with an entirely local crew is starting off on a prospecting trip round to the west next week. The Manager of the Queensland Company states that his Company attach no importance to the opinions expressed by these divers. Every one agrees that the period of the north-west monsoons will be much more favourable than that of the south-east now blowing, as the water will be much clearer. Pearlshell beds exist to the eastward of us in Torres Straits, and have been worked for years. They exist also to the westward on the Western Australian coast, where there have been rich and continuous yields. Pearlshell to the extent of about twenty tons have been taken from the bed of Port Darwin Harbour during the past few months. It is incredible, therefore, that our great stretch of coast, with its numerous islands, is a total and blank exception.—*South Australian Register.*

PLANTING IN THE LOWCOUNTRY OF CEYLON.

(From a Correspondent.)

Henaratgoda, 3rd September 1884.

WEATHER.—Here, as elsewhere, the rains of the S. W. monsoon have failed, to the probable extent of two-thirds, but July and August have been specially dry: from the 9th of the former to the 27th of the latter month there were only four light showers, not more than one inch altogether. On the 27th there was a shower, and on the 28th there were several light genial showers, every drop of which the thirsty ground drank greedily, and there is now the promise of more.

LIBERIAN COFFEE.—There was a promise of a tolerable crop of coffee early in the season, but a fresh attack of fungus and the recent drought together have taken off a very heavy percentage. I now believe that even without H. V. this product would never have been a good investment. Even when on good soil it has escaped the pest, and become a tree ten feet high and eight feet wide, with a large mass of healthy foilage, I could put its whole crop in my pocket.

CACAO.—After a five years' battle, I am defeated along my whole line. The legions of the winds have peppered me in front, the demons of the soil have ruined my commissariat, while masked batteries have played on my forces from all directions, and a disastrous retreat is all that is left to me. The last charge routed me, horse,foot and artillery. Whatever may be the source of the disease, it has been most destructive here: while most of the feeble strugglers have been blotted out, the finest and strongest have not been spared. It is hard to believe that the mere puncture made by an insect on the extremity of a twig will be so poisonous as to carry gangrene into a strong branch, and down that into the stem. Without denying the agency of insects in helping on the disastrous state to which the cacao trees are reduced, I only give it a place among many causes. If planted where wind can reach it, either directly or otherwise, the death of the plant will take place sooner or later according to the quality of the soil; if planted on indifferent soil, but well sheltered, it will struggle long and die at last. A long spell of either wet or dry weather is equally bad for it; insects of sorts attack it in every stage of its existence, and it is, in truth, the most delicate of all cultivated plants, though one of the most profitable to grow where all the conditions of success are present or can be produced at a moderate cost, but where any of the conditions are wanting, better let its cultivation alone.

TEA.—The tea planted here last year has had a bad time. It had hardly made a start when the dry season of four months came on it, and again within the year it has to stand another spell of two months' drought. It is very unequal, but on the whole it looks healthy, and will no doubt get on rapidly, now that we have rain. This year's planting has not been in luck: the spells of rainy weather have been so short and the intervening sunshine so long that they have been having rather a bad time, and a corresponding proportion have succumbed; but the tea plant dies hard, and many more of them are alive than could have been reasonably hoped for. The plant, however, that has been hardly used by the weather before getting a firm hold of the soil resents its treatment, by hanging back in its subsequent growth. The perfection of planting weather is no sun and frequent light showers for a week after planting, and we have had no such weather either this or last season. On the 27th ultimo we had rain; we had more on the 28th, and on the 29th it rained for 3 hours in the middle of the day. I knew all the risk, but the temptation was irresistible, and I put out 5,000 plants in in the afternoon. It rained a good deal in the night, and the 30th was a wet morning, so I put out another 5,000. On the 31st there was much sun and little or no rain, and when the morning of the 1st September rose bright, I was in a very despondent mood, but it rained heavily before two hours were over, and copious showers have been falling at intervals ever since, so that this last batch has been as fortunate as any other put out this season. Many failures there be, no doubt; that is however an institution in this climate, and, if we wait for very good planting weather, we will not plant at all.

PEPPER.—I have only half-a-dozen pepper vines in fruit; but the crop of these is so encouraging, that I have been endeavouring to attach a vine to every standing tree, but the deficiency of moisture has rendered my success of the smallest, not five per cent having lived through the last two dry months, and I have the work to go over again. It may be noted that nearly all the vines planted close to jak trees have lived, and nearly all those planted by other trees are dead. The training on rocks is not on the whole satisfactory, but they do become attached, after many failures, in proper aspects, and on perpendicular faces; they utterly refuse to grow on sloping faces.

IMBUL (*Tree Cotton*).—I sowed about a thousand imbuls at stake, but the long drought has been too much for them, and the few survivors look very seedy. Those planted last October begin to be a feature on the place, the most forward being ten feet high. There is no tree that sooner becomes large enough to train a pepper vine on, but whether it is otherwise suitable for this purpose remains to be tried.

CARDAMOMS.—It appears that cardamoms are not likely to make our fortunes in this part of the country. The planting done last October grew well for a time, and lived through the dry season, but one-half died when the first rain came, and the survivors have grown little since, and his season's planting (seedlings) nearly all died. I suppose the soil and climate are not suitable and that the shade is not dense enough.

CEARA RUBBER.—The Ceará rubber may be put out of court now, I think. I cannot by any means get enough of produce to cover the cost of collection, and, so far as I can learn, other people are in the same case. Tea must now take the place of that and all our other failures.

"KAPOK" AND MUDAR FLOSS.

In addition to the large amount of information we have already given regarding the short-stapled cotton which is known in Java and the countries to which Java has so largely exported it as 'kapok,' we now give a translation of Van Gorkom's article in his work on Netherlands India agriculture. There are several reasons why the cotton *tree* is so common in Java. It is used as supports for pepper vines, but beyond all the cause of its great increase was the use of posts and trees for the electric telegraph when first introduced. Iron posts are being gradually supplied, but the kapok trees (every post having grown into a tree) remain and yield crops of the flossy substance so well suited for the stuffing of mattresses and pillows. We are surprized, that, in his description of the tree, Van Gorkom failed to notice what is a marked peculiarity of its mode of growth: not only are the branches thrown out in horizontal tiers, but it is the rarest possible occurrence to have either fewer or more than three branches in each tier.

We give also a translation of the Dutch writer's notice of *mudar (Calatropis gigantea)* and we add an extract from the *Treasury of Botany*. But certainly it is news to us that a bush of the mudar plant will yield more floss than a cotton-tree. Whatever may be the case in Java, we do not think it is so in Ceylon. The plant is common and widely-distributed in India and Ceylon. In the North-Western Provinces of India the mudar abounds on poor undulating lands where it seems specially to flourish. It is quite a feature in the landscape around Muttra and Agra, and, if anywhere, it ought to be there utilized for the floss and stem fibres. As far as Ceylon is concerned we have more hope in the fibre than in the floss, but for this as for all fibrous plants a good machine is wanted, such as has not yet appeared.

KAPOK.

(Translated for the "Ceylon Observer" from K. W. Van Gorkom's "Oost-Indische Cultures.")

If the export of Netherlands East India cotton is of such small importance that the official reports of Java and Sumatra do not even mention the article,—of *kapok* it was stated, there were exported, in the years 1875-9, from Java, 305,027, 419,782, 865,973, and 1,009,239 kilograms, which was taken for the most part by the Netherlands. The exports from Netherlands India (customs department) was inthe years 1877-8 successively 1,038,696, and 1,001,274 kilos, the value of which was estimated respectively at 40 and 36 cents per kilo. According to the commercial reports there were brought to market at Amsterdam and Rotterdam, in the years 1877-9, 14,093, 10,519, and 12 050 bales. The exports consisted largely of uncleaned kapok, which does not so readily meet with buyers, and for which, also, naturally, less favorable prices are offered than for the cleaned product.

Although the kapok is a handsome, white, fine wool, it has hitherto not been possible to utilize it in the spinning and weaving establishments, but it is more and more valued as a stuffing for cushions and mattresses in substitution of the costly down.

The *kapok* or *randoe* tree *(Eriodendron anfractuosum)* belongs to the family of the Sterculiaceæ, and, although originally a native of South Africa, is met with extensively in Java and Sumatra. Teijsmann found it also in Timor, and it is certainly more generally distributed. It is 50 feet high and more, and forms a thick straight stem with few branches, which stretch far out perfectly horizontally in the form of a crown, The tree has few leaves, looks very bare in the dry season, and produces long dry fruits, which when fully ripe split open and show the pure white wool in which are enveloped the black seeds above the size of a pea.

The tree is found distributed throughout Java, in the gardens and along the roads. The natives have for ages past used the wool as stuffing for their cushions. The tree had special attention paid to it at the time of the telegraphic communication being projected in Java (1853 56), when suitable trees for posts were sought for. After many experiments the kapok tree appeared to be the most suitable, and it has, with excellent results, been also used for the extension of the lines in Java and Sumatra.

Although the tree is not deeply rooted it stands pretty firm, as its crown offers little obstruction to the wind. Moreover, it is not particular as to soil, and thrives well at 4,000 to 5,000 feet above sea. It is grown as easily from cuttings as from seed, and the natives assert that it attains to an age of 5 to 50 years. Even large stems, such as are used for telegraph posts, can be cut and planted with hope a good results. If in dry weather the ground is kept moist, such a sump will will send out roots speedily and grow uninterruptedly. Twenty-five years ago the telegraphic service in [Netherlands] East India recommended the kapok stems on account of this facility of growth: this fact speaks for itself. Since iron has become cheaper iron posts have come into use, Batavia, the capital, setting the example, and following the example of our Australian neighbours eucalyptus stems will also have a trial. The needs of the telegraphic service gave a great push to the increase of kapok trees. Along the roads and on waste patches near the *desas* [villages] have risen everywhere in Java small plantations. Within three to five years' time from seed or cuttings are raised stems which can be used as wire-bearers. The extension caused a considerable increase of wool production, and since the kapok has begun to be valued in Europe more care has been taken for a periodical and thorough gathering, to meet the increasing demand. Meanwhile, it will never enter the mind of a European planter to undertake a special culture of kapok trees. The trees require too much room and yield too little in proportion. Along roads and also in tea and other plantations, however they might well find a place, and might serve as land-mark, from which at least for domestic use, a valuable product can be got. From the seeds de Vrij obtained by expression 8·9 per cent, and by extraction with benzo-18·6 per cent of a yellowish oil, clear as water, with a pleasant taste, and which, according to Oudemans, who differs from Maier, is not a drying one. Oudemans found in this oil 75 per cent of oleine and 25 per cent of tri-palmitine and tri-stearine.

Closely resembling kapok wool is the silky seed down of the *Calotropis gigantea*, belonging to the family of *Asclepiadeæ*, and known in [Netherlands] East India as *widoeri*, *badoeri*, *sidogori*, &c., and in British India *mudar* or *moddar*. The widoeri wool is also used at present solely as filling for cushions and mattresses, which are in great request on account of their coolness and fetch high prices. The widoeri is met with plentifully in [Netherlands] East India, growing wild; especially on dry grassy tracts on the slopes of the mountains and along the shores. The plant attains to a respectable girth, has broad, copper-green leaves and rose-violet flowers, on high, thick stalks, which yield a very strong fibre adapted for all kinds of weaving; it is a perennial and yearly ripens the fruits which contain long, soft, silky down, the so-called widoeri wool, as appendages of the seeds. It is asserted that a plant will yield annually 3 to 4 pounds of clean wool; the quantity of down from a single fruit is said to be 0·8 to 1 5 grams. Thus the plant yields considerably more wool than the cotton, and the cleaning of the seed-down is very easy. The widoeri is found plentifully wild and in all soils even the poorest; it is therefore not very sensitive nor choice, and its systematic culture would cost little care or trouble.

In each case we think that more attention might well be paid to the gathering of the wool of wild plants.

Calotropis.—A genus of Asclepiads, consisting of three species, which form shrubs or small trees, and are natives of the tropics of Asia and Africa. Their flowers have a somewhat bell-shaped corolla, expanding into five divisions, the tube being composed of five angular swellings. The coronet of the stamens is composed of five narrow leaflets, which are united to the central column, but free and recurved at the base, with their edges rolled inwards. The fruits are produced in pairs resembling the horns of an animal, each being swollen or bulged out on the inside; they contain numerous seeds surmounted by tufts of beautiful silky hairs. *C. gigantea*, the largest of the genus, forms a branching shrub or small tree about fifteen feet high, with a short trunk four or five inches in diameter. Its leaves are about six inches long by two or three broad, and egg-shaped covered on the under-surface with soft silky down, and they are arranged on the stem in pairs, each pair being at right angles with that above and below; its flowers are of a pretty rose-purple colour, and have the segments of the corolla bent downwards. The plant is called Mudar or Ak in Northern and Yercum in Southern India. The inner bark of its young branches yields a valuable fibre, capable of bearing a greater strain than Russian hemp. All parts abound in a very acrid milky juice, which hardens into a substance resembling gutta percha; but in a fresh state it is a valuable remedy in cutaneous diseases. The bark of the root also possesses similar medical qualities; and its tincture yields *mudarine*, a substance possessing the property of gelatinizing upon the application of heat, and returning to its fluid state when cool. Attempts have been made to spin

the silky down of the seeds, but its fibre is too short; a soft kind of cloth is, however, made by mixing it with cotton; paper has also been made from it. Another species, *C. procera*, a native of India, Arabia, Persia, and various parts of Africa, possesses similar qualities. It is a much smaller plant, and has white flowers with straight segments.—*Treasury of Botany.*

THE CURING OF FISH IN THE MADRAS PRESIDENCY

is progressing satisfactorily in the yards, to which salt is supplied at exceptionally low rates. The following letter from W. A. Willock, Esq., Acting Commissioner of Salt Revenue, to the Secretary to the Board of Revenue, dated Madras, 20th May 1884, contains much valuable information, which we hope may yet be turned to account in Ceylon :—

I have the honor to submit the information regarding the variations in the proportion of salt used to fish cured. I regret that the fact that it had been called for escaped notice.

2. These variations are due to two causes—ignorance on the part of the curers of the value conferred on their produce by the use of a liberal allowance of salt while under preparation, and differences in the kinds of fish operated on and the method of curing employed.

3. As regards the first of these causes, the fishermen evince a great disinclination when they first resort to fish-curing yards to spending money on what they have hitherto been accustomed to obtain for nothing in the shape of salt-earth, and they, in consequence, endeavour to perform the operation of curing with the smallest possible quantity of salt: but as time goes on and they find that their fish sells and keeps the better for the use of a liberal allowance, they treat it less sparingly, and the proportion rapidly rises. This is shown very clearly by the general results given in the reports for the half-years ending 31st March 1883 and 30th September 1883. In the statement printed in the former, the two lowest rates were (excluding a single operation in South Canara) 6·88 lb. and 6·67 lb. of salt per maund of fish in Nellore and Chingleput —two districts in which operations had only just commenced. The third lowest rate—12·54 lb.—was also in a new district (the Godavari) while in those in which yards had long been established, Ganjam, Kistna, Madura and Tinnevelly, and in Malabar, where the experiment had met with great success, it varied from 14·78 lb. to 20·72 lb. In the following half-year, while no very great change took place in the proportion in the last-mentioned districts, the rate rose to 14·91 lb. in Nellore and 11·33 lb. in Chingleput, while it was lowest in Vizagapatam (11·04 lb.)—a district which made its first appearance on the list.

4. That differences in the methods of curing adopted may be expected to give rise to enormous variations will be apparent from a consideration of the following two processes. They are extreme cases, but are both very common. At Calingapatam, in January last, I was present when a large take of very small fish was landed. They were thrown, just as they were, into large earthen pots, without having the entrails removed. Some salt was then thrown on the top and the pot filled with water. After soaking for an hour or so, they were removed and dried in the sun. In another process the fish are cleaned, split open, and, if large, gashed along the sides, and salt is well rubbed in. They are then packed in a hole in the ground, salt being placed between the layers. A mat is laid on top and the mass covered up with earth. After a day or two the fish are dug up and dried in the sun, and are then ready for use. A heavy expenditure of salt might naturally be expected here. Various modifications of this process are common in the Tinnevelly district, where the proportion of salt to fish ranges very high. Another very extravagant method is referred to below. In all these processes, the size of the fish makes a great deal of difference, and the state of the weather and the freshness or otherwise of the take also considerably affect the quantity of salt required.

5. It is somewhat rash to hazard an estimate at present of what the minimum quantity of salt required to cure the average description of fish brought to an average yard really is, but what little experience we have as yet acquired would tend to show that from one-seventh to one-quarter of the weight is required, and if abnormal proportions of very large or very small fish are cured a little more or a little less would be necessary. If this view be accepted as correct (it is supported both by general results and individual inquiries), all cases in which more than seven maunds of fish are cured with one of salt may be disregarded as merely indicating inefficient treatment, owing to ignorance on the part of the fishermen; and the only yards referred to in G. O., dated 12th September 1883, No. 1,119, Revenue, that would require further notice would be those of Sonnapur and Gangoli, where the weights of fish cured per maund of salt were 2·8 maunds and 2·03 maunds, respectively. The Sonnapur yard was one of those under the extra departmental supervision which has been found to work in such an unsatisfactory manner. A few months back, the superintendent was discovered to be so careless and to neglect his work so much that other arrangements had to be made for its charge. I have no reason to suppose that any fraud actually took place beyond the pilfering which carelessness would be likely to give rise to, and the proportion of salt used does not even show that anything of the sort did occur, as it appears that the fish were rarely weighed, the entries made being merely estimates and possibly very incorrect.

6. The proportion at Gangoli is capable of a very satisfactory explanation. The process used there is very peculiar, the fish being, contrary to the custom prevailing elsewhere, salted entirely in the shade. The persons who operate are fishermen who come from Rutnagherry, and as the drying power of the sun is not made use of several applications of salt are necessary.

7. Instructions were issued some months ago directing the institution of experiments in fish-curing by the officers of the Salt Department with a view to introducing improved methods of preservation. I regret to say that the officers concerned have found but little time to devote to work of the sort. The latest reports on the subject have not reached me yet, but I hope to find that success has attended the attempts of some of them. A trade which has displayed such enormous powers of development as that in salt fish has during the past few months, will need but little help and attention to ensure a very great improvement in the quantity of the article produced. The results of the past half-year, during which not far short of three lakhs of maunds have been cured, have been so encouraging that the officers of the department are beginning to take great interest in the matter, which is certain to produce most advantageous results in this direction. The great bar to the introduction of improvements at present is the want of a demand for a superior article, but there are good grounds for believing that this is rapidly being developed.

8. With regard to the yards referred to in the Government Order under reply, I venture to observe that if my views on the subject of the proportion of salt required explained above are accepted, the only rates referred to which require further notice are those at Baruva, Ramapatnam and Adirampatnam. Information has been called for, but I have no doubt but that extra departmental supervision is in fault in the first two cases. With one or two exceptions, where the transactions were very small indeed, these are the only yards at which the rates were suspiciously high.

9. The loss entailed by buildings being erected and establishments maintained where no fish-curing is done will receive due notice in the next report, but I would explain briefly at present that this is unavoidable in the case of new yards (*vide* also paragraph 4 of Mr. Bliss' letter). The fishing classes are inordinately suspicious, and having peculiar reason to regard the operations of the Salt Department with aversion, it takes them a long time before they become accustomed to the existence of a yard and its officers in their midst. Their first feeling is that, if they persistently avoid having anything to do with it, it will at last be removed; but a large take of fish or other chance circumstance suddenly changes all this and work goes on satisfactorily afterwards. The Canara yards form a case in point. There is not the slightest reason to suppose that they will not eventually be as flourishing as

those in Malabar, but for several months at first they were absolutely idle, and many seem to be failures still. Yet to close them for this reason alone would do away with all prospects of future success. The Polaram and Pudimadaka yards, in Vizagapatam, were avoided in the same way for many months after their establishment. The first fish cured there was brought in the latter part of the half-year ending 30th September 1883, but during the half-year which has just passed, they cured 1,450 maunds and 1,846 maunds of fish, respectively. This, however, is not the invariable cause. It was not to be expected that officers with no experience of the fishing trade could avoid placing yards in the wrong position occasionally, and many have been idle in consequence of mistakes of the kind which can only be found out by experience, but steps are being taken to weed out all such. In fact, this has been done in the Northern Division, all the yards now maintained in which have, as far as can be seen, all the necessary elements of success Fifteen of those referred to were within its limits. Several of these have since been abolished or removed to better sites.

MACHINERY FOR PLANTATIONS.

[In quoting what follows from the Supplement to the *European Mail*, we feel bound to say that there is, as yet, no satisfactory evidence that the fibre machine is the success it is represented to be.—ED.]

Towards the close of last year brief reference was made in these columns to the new fibre-cleaning machine invented by Mr. H. C. Smith, which, at the suggestion of Dr. Forbes Watson, was successfully applied to the preparation of rheea. Practical experiments subsequently conducted with this appliance by Dr. Forbes Watson, both at home and in India, have so amply confirmed the favourable opinion formed by experts in regard to it that we deem a more detailed description of its character and purpose will prove acceptable to our readers. In the first place, we may say that the value of the machine is by no means confined to one quarter of the globe, for it extracts and cleans the fire, not only of rheea, but of jute, hemp, agave, pine-apple, and the phormium tenax, or New Zealand flax, as well as all other fibre-producing stalks and leaves, when treated in a green and freshly-cut state. Hitherto a difficulty has been experienced in preserving the natural whiteness of the fibre from discoloration by the sap or juices which exude from the growing plants. By the new machine these juices are at once washed out of the fibre by means of a thin sheet or flattened jet of water, the quantity and force used being regulated according to the condition of the leaf or stem operated upon. This jet or stream of water plays upon the fibres, at the same time holds them up to the action of the beaters, forming a species of elastic cushion or backing of water during the operation. This is not only a rapid but a peculiarly economical process. The whole of the pieces, as well as the green bark and the broken up stalks of the exogenous plants, and the pulpy and the other adherent matters of endogenous fibre-yielding leaves are at once removed, and the fibres, of which there is no waste, are extracted in their natural state, and only require to be dried and baled for exportation. The manipulation of the machine is so simple that it can be readily worked by a ryot or any unskilled native labourer. Moreover, it is particularly well adapted for use in different countries, from its extreme durability and freedom from liability to get out of repair An illustration which we append will show the general appearance of the machine, which we may say, promises, by giving considerable commercial value to several hitherto unmanageable fibrous plants, to mark a new era in the prosperity of Indian and colonial planters. The sale of the machine lies in the hands of the General Fibre Company (Limited), of 141 Fenchurch Street, London, who also furnish the necessary plant, engines, mills, baling presses, horse gear, &c., for the establishment of fibre factories on any required scale. In this the company, who have the assistance in their operations of the counsel of Dr. Forbes Watson, who acts as their technical and scientific adviser, as well as Major-General Frederic Cotton, R. E., C. S. I., Mr. W. E. Death, and other competent engineers, furnish general machinery for colonia farms and plantations. Their list includes one or two appliances of peculiar character and value, which are also deserving of mention here. Martin's new patent rice and general grain decorticator, manufactured by W. J. & C. J. Burges, and which is sold only by this company, is claimed by them to be the most perfect appliance yet introduced for decorticating shelled rice, Egyptian dari, Indian jowaree, and Bajra wheat, and all similar grains, whose outer skin or cuticle should be removed before being used for food It is made in three sizes, for hand, steam, and bullock power respectively, and the smallest implement, which is easily driven by two men, decorticates per hour from ½ cwt. to 1 cwt. of rice, dari, or wheat, according to the nature of the grain. Its leading characteristics are the slight power required to drive it—a feature borne out by the statement just made; the equality with which each grain is decorticated, and the saving in breakage, the damage in the case of some grains being almost *nil*. To these recommendations are to be added the special simplicity of its construction, its durability, and the fact that the material from which it is made adapts the mill to any extreme climate. Another appliance worthy of note is a patent safety bullock gear, in which has been overcome the two great difficulties in the way of producing a satisfactory bullock gear, namely the slow step of these animals as compared with the horse, and the unevenness and unsteadiness of their walk. The construction of this gear, is based upon lines indicated by Dr. Forbes, the late Cotton Commissioner to the Government of Bombay, as also upon the sults of a series of trials recently carried out by Dr. Forbes Watson, both in England and in India, and of experiments by Mr. A. Stormont, the Superintendent of the Government Experimental Farm in Khandesh, in the Bombay Presidency. To quote the company's own words, which afford the best description of the appliance, "with the gear worked by bullocks travelling at the rate of one mile and a quarter per hour, the lay-shaft gives 150 revolutions per minute, a speed equal to that obtained with steam, whilst steadiness in working and the full effects of the exertion of the animals are ensured from the manner in which they are yoked. Steadiness, with a minimum amount of friction, combined with durability and safety, is also secured by the perfect balancing and adjustment of the main gearing. By having the whole of the main working parts enclosed in a cast-iron cylinder, the entrance of grit and dirt, so objectionable in all open gears, is prevented, and safety to itself and to the cattle and work ensured, whilst at the same time access to the interior for lubrication or other purposes may be readily obtained." The gear is arranged for using from two to six bullocks, according to the work required. It is also admirably suited for hard-labour in prisons, the amount of pressure exerted by each man being indicated by a gauge. Among other appliances of the General Fibre Company (Limited), to which we have not space to refer at length is an improved "Persian wheel" water-lift, constructed on the principle widely adopted in India, Egypt, Spain, &c. for raising water by means of bullock or other animal power, and an emery patent saw cotton-gin, which was awarded, at the Calcutta Exhibition, a first-class certificate and silver medal—the highest award for cotton-ginning machines—and which has subsequently been considerably improved by the addition of a new patent condenser.

PROSPECTS OF COFFEE PLANTING IN WYNAAD.

I would ask my fellow coffee planters to aid me, through your columns, with their views as to the future of that industry, which is at present th support of ourselves, our wives and children. I have just completed an examination of the prices realized for the past season's coffee from my own estate, and that of several neighbours, and I find that, after allowing for exchange, I have secured under R600 per ton on board a ship in India; and from this we must deduct the crop and curing expenses there is, say, R450 left me, or a shade over R22 per cwt. There are two great points to look to: 1st.—What weight of crops can I calculate on? 2nd.—What price may

I expect? In regard to the first I consider 3 cwt. an acre a very full quantity; in fact, since leaf-disease came I have not done that on an average and I am satisfied that most of my neighbours are not one bit better off. Next as to price, the point on which there will be the most difference, as men will hope against what is as near a certainty as any thing under this sun can be, and that is that we are likely to have for some years to come a low level of prices. This fall in price has been evident to all who have watched what has been passing. Brazil and other coffee-producing countries have had railways laid on, opening the country out, permitting their coffee not only to be brought down at a less cost, but in better condition; and all their expenditure has been favourably affected, while we in Wynaad have not secured grace in the eyes of our masters, and have had our communications neglected until they became impassable and a scandal, and all aid in punishing defaulting maistries refused. So if my brother-planters will accept my views, that R22 is the highest net price on the trees that a prudent man can calculate on, and 3 cwt. an acre—really more than fact—we come to a return per acre of R66. My estate cost me a shade over R300 per acre, and by the kindness of relatives in England I was able to borrow at 5 per cent., a rate below that most men can secure money; so I have an annual interest of R15 per acre to pay plus that on current expenditure, which for purposes of account we will call R1—it is really much more. So I came to a deduction of R16 for interest, leaving me R50 to cultivate the estate and keep myself. R50 will not do it. I see myself steadily falling into debt, not only to the detriment of myself but my relatives, and my feeling is to throw up the sponge, abandon my estate,—for I can find no one so foolish as to buy,—and bid farewell to the Wynaad, where I have spent so many happy years, and try pastures new. But before doing so I would thank my brother-planters who would show me how to hold on at a profit. Do not let them bark at me with cinchona; have I not seen them planted over vast areas leaving scarcely a vestige of their existence behind. Cinchona, like other useful things, has served its purpose; it staved off from many a poor planter, the day when his coast agents would advance no longer. That day has now come, and cinchona extracts no longer money from them. One last word in conclusion as to the coast agents, a body much abused my many a borrower; but to my mind they have always conveyed the idea of much philanthropy; they have supported over many years many well-deserving men who, under much more favorable circumstances, could never have succeeded, and every Coast agent must be a poorer if not a wiser and sadder man. As far as I can see, the absolute extinctio of the Wynaad planter and those dependent on him, such as curers and such like, is within measurable distance; and although a planter, I think I may safely say that our loss would be a real loss to others than ourselves.—V. R.—*Madras Mail.* [Not a word about tea.—ED.]

SINGAPORE VEGETABLE TALLOW.—According to a correspondent, the above tallow is a white, firm brittle mass, which becomes soft on being kneaded between the fingers, is pasty between 81 deg. and 140 deg. Fahr., and melts at 116 deg. Fahr.; it is soluble in cold ether, but less so in cold acetic ether and pyro-acetic spirit. It is, however, easily dissolved in these liquids when they are warmed; it is soluble in half its own weight of cold chloroform, and in one-third its own weight of heated chloroform, while sulphuret of carbon in either condition readily dissolves it. This tallow is produced from the seeds of a tree which in India is called *Mingaktangkawand*. This tallow is said to be superior to olive oil for the lubricating of machinery, and it is also used in Manilla for making candles; it yields glycerine, and about 95 per cent of sebacic acids capable of being saponified.—*Independent Journal.*

PEPPER ADULTERATIONS.

With the advancing market for all grades of pepper the subject of adulteration is more prominently brought to the attention of those interested in this article. We were the past week shown the price list of a prominent grocery house in this city in which brown pepper was quoted from thirteen to twenty cents per pound, the latter presumably pure, but what could be the composition of the stuff offered three cents below the jobbing price of the crude article? Pepper dust, pepper shells and mustard hulls have long been used as adulterants, but the quantity of these obtainable is not sufficient to meet the demand, and recourse has latterly been had to other and more objectionable substances. We know of an instance where twenty-five tons of pepper dust and sweepings were purchased by one concern which pretends to sell nothing but pure ground pepper. This stuff has a market value of five cents per pound, and is little better than the ordinary dirt swept up from the floors of a spice mill. Cocoanut shells are also ground up and mixed with pepper, and it is asserted that ground segar boxes, which were used in Germany a few years since, and there prohibited by special legislation, has recently been used here as an adulterant. The law here prohibits the refilling of empty segar boxes, and these can be secured at a nominal price and are said to be more satisfactory to the adulterators by reason of the difficulty of detecting the adulteration and the pungency of the material. Segar boxes are acceptable articles when they contain fine flavored Havanas, but ground up and mixed with pepper to be eaten is repugnant to a sensitive stomach. We would suggest the propriety of an investigation of the quality of the mixtures offered for sale as pepper to the authorities acting under our recently enacted drug and food adulteration law. Coloring coffee to make it look better and sell more readily may be objectionable and should be prohibited, but while the Boards of Health and other authorities are directing their attention to this comparatively harmless deception and publishing their efforts in this direction with a great flourish, they are paying no attention to the greater and rapidly spreading evil of the adulteration of pepper.

Let the State analysts secure samples of ground pepper advertised to be sold at prices at or below the market value of the crude berry, and analyze the same, and we have no doubt they will find much more to condemn than they have yet discovered in the practice of coloring coffees or teas. We would further suggest that the names of the parties who adulterate pepper, as well as the substances used, be given to the public, that they may be held up to the just execration of a deceived people. In this way the practice of adulterating articles of food and of drugs can be checked much more effectively than by simply notifying the guilty parties or imposing a nominal fine. It is important that this matter of pepper adulteration receive prompt attention as it is a growing evil, and since the advance of the pure article, the practice has received a fresh impetus, and promises to grow to proportions not reached during the high war prices of twenty years ago, unless checked by exposure and proper punishment.—*Independent Journal.*

FOREST CULTURE.

(*Continued from p.* 686, Vol. III.)

The heart of a full-grown djati-tree is proof against white ants, the rest of the wood not; though it be generally eschewed by these troublesome invaders whenever they can get possession of any other wood, less bitter and more to their liking. Nor does the djati offer but a partial resistance to the so-called *paa'-worm.* (*Verslag en Mededeel. van Kon. Akad. va. Wetens. Afd. Natuurk.* IX. 25). Most other attacks and injurious influences remain powerless upon the djati, yet it must not be dissembled, that the former more limited felling, when the selection of fully matured, vigorous and really fit timber was carefully attended to, furnished generally better timber, and the tradition of the djati woods's exemption from dry-rot, etc. handed down to us from the time of the former

East India Company, may then have had some foundation. And it may well be doubted whether such results could now be obtained with our present timber—the produce of free traffic—as for example such ships as the English "Resolution" and "Canopus" which reached an age respectively of 128 and 84 years, or as our Dutch "Javaan" launched in 1822 at Bandjar (Toeban, Rembang) as a corvette for the Colonial Navy, later long commanded by Capt. Dekker as a merchantman, and which after 50 years' service, requiring no repairs worth mentioning, was engaged in the Indian coasting-trade—whether now still such temple-ruins, as Ritter mentions (Erdkunde, Asien. IV, 813), of which teak beams had withstood, uninjured, for more than a thousand years the open air and the influences of climate. With previous or timely orders, and careful selection, this might, of course, be still possible, but then at comparatively high prices, formerly unknown, and with precautions of obtaining a gradual and equable drying, formerly not even suspected, but now become necessary by the evident modification which the climate has undergone by successive-disforesting. These and some other causes, taken collectively, render it at present impossible to furnish well-prepared timber at remunerative, or even acceptable, prices, especially for ship-building purposes. To this it is to be attributed that, among others, the use of djati for this can no longer contend with what it was formerly, and that we should be inclined to deem earlier accounts exaggerated, were not the contrary satisfactorily attested.

Yet the djati is still one of the best working woods we are acquainted with, durable, hard, and yet not difficult to work; more manageable, for instance, than good oak, not easily injured, very equal and long of fibre, elastic, and possessing great firmness and greater resistance to strain than any European species of wood.

Of all of these it most resembles oak, but is in general of higher value, and has, especially for ship-building, a very great advantage over oak, in that its specific gravity is less. The djati has been tried repeatedly, and in different periods and in different places, as to its specific gravity, solidity and elasticity, the results were, as was to be expected, rather various; but everything considered, more favourable than of oak. Reckoning the solidity, power of resistance against forces pressing vertically upon the direction of the fibre, of the latter at 40·6 K.G. per c. M² then the djati gives, according to the average of the trials made by Colonial Von Deutsch, 52·18 K.G. and Dr. Nordlinger obtained still higher figures. The last mentioned gentleman mentions (in his "Eigenschaften der Hölzer," p. 357, 371) the teak-wood in general as among the exceedingly elastic woods, and among them the djati as surpassing all European woods, &c., built too upon the trials of Barlow, who taking beams of equal dimensions (7 ft. long by 2 inches square) supported at either end, found that the djati required a weight of 425·27 K.G. in the middle to break it, while Canada oak broke with 305·12 K.G.

One of the most valued advantages, however, is the specific gravity, which, though here too the trials diverge, generally proved to be lighter than that of oak, stating the latter on an average at 0·791. Dr. Nördlinger obtained, as the average of his tests, 0·680; Colonel von Dentsch rather lower cyphers, (namely 0·659, 0·630 and 0·628 from three series of tests.—general average 0·639); M.M. de Bruijn 0·689, Delprat 0·692, Jordens 0·695*). Against these stands the statement of Mr. de Keurenaar, who fixed 0·816 (?)

Cordes in his in every respect trusty and elaborate work, already quoted, adduces all the data and literature on the subject, and adds graphic representations, also for the illustration of further particulars, such as the concurrence of a greater specific gravity with greater firmness in one and the same sort of wood, at different heights of the same trunk, and some others, which fall beyond our present limits, but taken all together constitute an interesting whole.

The cyphers given above, the consequently greater floating power, the little liability of splitting when exposed to climatic influences, all the other qualities already summed up, justify the eminently favourable opinion prevailing in general about the Djati wood as a building and working material, and for ship-building in particular, expressed everywhere and almost unanimously by good judges. Yet the balance, the complete co-operation between the several branches of production and industry, was not generally attained by us, and such was also the case with the felling of the djati. Most of the dimensions observed in felling answer indeed the purposes of the native ship-building, but not those of European, and this is one of the causes why it is so little used in Europe, and especially in our Netherland shipbuilding yards.

In conclusion I must observe that as with some other verbanaceæ, the young shoots and leaves of the djati contain a reddish brown dye, which is occasionally used for dyeing wood.

Java, at least the central part, and chiefly the eastern, was originally overgrown with djati woods. The centuries of misgovernment, or rather of destruction by the native population, the government of Java came by degrees under our rule, and we saw ourselves placed, with regard to these djati forests, or rather what remained of them, face to face with an intricate and comprehensive, but especially for us, unknown-problem. There had been no lack of counsels and hints—among the rest of Mr. P. G. Van Overstraeten, in 1796, and especially of D. Van Hogendorp in 1799, nor of good and telling measures, though abandoned by force of circumstances—those of Daendels in 1808—1811. The disastrous results of the succeeding half-century, the results of trials and regulations in various directions, in fact of neglecting and damaging the whole business, we will pass over. The Governor-General Sloet van de Beele proclaimed by St.bld. 1865 No. 96, the "*Ordonnantie*" of 10th Sept. 1865, for the management and culture of the Forests of the State in Java and Madura," in which the claims of private interest were fully regarded, and the principle of free labour—thus the abolishing of the blandong-system—was carried out.

In the very next St.bl. No. 97 was added to this "Ordonnantie" a Manual for the cutting or felling, testing and measuring of djati-wood"; and a "Manual for the planting and training of dajati trees in the Forests of the State, in Java and Madura.

A turning point in the history of Forestry!

Those "*Ordonnanties*," indeed, proved to have still many shortcomings, but the impulse was given, and the improvements soon followed, contained in a number of amplifications, and which soon ended in the withdrawal of the "*Ordonnantie*" of 1865, and the promulgation of a new "Ordonnantie" for forestry, containing a "Regulation for the management and Culture of Forests in Java and Madura, St.bl. 1874, No. 110." This was enacted by Decree of 23rd March 1875, St.bl. 1874, No. 84, on May 1st 1875.

It is this Regulation that now governs the whole affair.

As principle was adopted:—

"That the forests be distinguished into djati woods and savage woods.

"The djati-woods are all brought under a regular management.

"The cultivation of all the djati-woods, and of the wild-wood forests brought under a regular management, takes place by means of private industry in two ways:—

a. With the free disposal of the wood by the planter, against a payment of a sum according to agreement; or

b. With delivery of the wood to the Government, against payment to the owner of a fixed amount for expenses of cutting and conveyance per Cub. Metre."

The minutes of the condition upon which the cultivation of the Forests of the State in Java and Madura are undertaken, are inserted in the *Bijbladen* No. 3,230 and 3,389 while in St.blds. 1875 No. 119 and 1882 No. 149 some modifications were made in the Regulation.

In preparing the "Ordonnantie" of 1865 a resolution was passed in 1859 to have the djati forests surveyed and mapped out. In 1860 a Commission was appointed for this purpose, who in 1871 were almost ready with their task. The main result of this was that our Government had the disposal of more than six millions of *bunders* (6000 K.M²) of djati forest-land. If there were among these unimportant, inaccessible, or otherwise worthless portions, yet on the other hand the regular Government plantings, among which some of considerable value, were not included.

* My own tests with Djati soengoe and lenga, gave 60·69,121 as the average of a pretty large series.

The Residence Rembang is here foremost; its djati woods, both for extent and excellence, are equal, if not superior, to the whole remainder of Java.

Both forestry and the forest police had in the beginning a difficult task, both as to the eradication of abuses and the prevention of trespasses; they can now show with complacency that the condition in these respects is visibly ameliorated. With equal complacency can the results be pointed out of a regular cultivation, the felling and planting anew by parcels at a time, which has already given some thousand *hunders* (in Rembang alone 3,200 H.A.) of new, pure, young djati wood, with vigorous straight young trees of equal age and growth; a considerable capital for the future.

The system adopted in 1865, greeted with approval by private industry, created, however, along with the commercial and speculative spirit, some great oscillations, from extravagant, nay sometimes inconsiderate confidence and venturesomeness, to equally great and mostly uncalled for despondency. The balance is not yet quite restored, and consequently the production on a vast scale and for the European market is depressed.

The whole number of concerns for djati-wood cutting in Java and Madura amounts now to 31; the smallest of which in Japara has 61 H.A. (87 bahoes), the largest in Madioen, 1,707 H.A. (2,700 bahoes), altogether in Java (in Madoera there are none), 14,606 H.A. (20,724 bahoes) of djati-woods in cultivation.

And does the "Ordonnantie" of 1874 now give an ultima ratio upon the system to be followed? We cannot say. Burning questions start up, and now and then take the lead, such as the one about "the cultivation of the djati forests with free labour on Government account."* Speculations about this and other questions concerning our subject, and the probable future of the djati-forests and their cultivation under any of these systems are outside our plan.

Over against the djati forests stand the collective so called *wild-wood* forests; the management and disposal of which was also regulated by the "*Ordonnantie* aforesaid of 1865. Applications for regular felling were not made hitherto by Europeans; nor did they become to them an object of forest-culture. They therefore fall behind our present plan, as likewise the mere temporary grants to the natives. A table in Stsbld. 1874, No. 110, gives the protected sorts, thereby more or less intimating their value.†

Among these so-called wild-woods, there are several that are very remarkable; either for their beautiful, fine grained wood, admirably adapted for all kinds of cabinet maker's work, or for the less high, but not less useful, purposes of daily life, commercial needs, etc., in the same manner as in Europe oak is not always deemed essential. What stands chiefly in the way of all these woods are the great claims for preparing, seasoning, etc., whereas in the djati this gives little trouble, which, together with lack of room and active capital, causes a scanty store, and thus an impossibility to satisfy all orders. Moreover these wild-woods are still too generally unknown and neglected.

The result of all this, however, is that now the Batavian native and the Chinese cabinet-makers (and their number is really not trifling) receive their wood for furniture, for instance the *Rengas* or *Iwas* (*Gluta benyes* and *semecarpus heterophylla*, closely related to the *Anacardieae*), from Singapore, ignoring Java and Sumatra, where it occurs every where, or from the *Rinat* of Ambon or Lassi of Ternate, equally good *Semecarpus sorts*. And with other species the same phenomenon is observable, an anomally which ought well to be taken into account, and this the more as the condition was formerly very different.—Java furnished, for instance, its Sana wood, *Pterocarpus indica*, a Papilionacea (Miq. I 135) as "Sun-wood." Ambon its Lingoa, a variety of the same species, as "Ambon wood," a delicate and durable cabinet maker's wood, to Netherland, where you might look for it in vain at present. And now still we have instances before us. Cuba sends its "*Magagua*," *Hibiscus elatus*, to North America (New-Bedford) to be laid, after being bent by steam, in a running fello round the wheels of his Américaines. Netherland might do exactly the same with the almost identical *Waroe goenveny*, *Hibiscus vulpinus*, which, however, notwithstanding completely successful trials proclaimed as much as possible, is not used even in Java. The felloes are sawn out of the slab, from the much broader *Waroe Gambong*, *Hibiscus tiliaceus*. And of this, too, we might adduce a number of examples. Change and improvement are here loudly called for.

West India possesses no Forest culture by Europeans in the above sense, and therefore we refer, as to the kinds of wood, to what is mentioned on this subject in Cl. 10, Lett. E, and especially to the Literature on this subject noted there. There, too, change, improvement, development are desirable, and much remains to be done still.—VAN MUSSCHENBROEK.—*Indian Mercury.*

* Vide the quoted work of Cordes, p. 130; further F. G. v. Bloemen Waanders: Must Netherland be ruled on conservative or liberal principles?; silvicola. A few observations on Forestry in Netherland India." (Tijds. v. Nij. en Landb. in Ned. Indië XXV. 366/81, 485/532) and others.

† An enumeration which might well be modified, or rather amplified. A few insignificant kinds are mentioned, and whole genera of the most useful overlooked. Thus the not at all general, but rather accidental. *Tjemara* called *Ki poetri*, the *podocarpus cupressina* (Miq. II. 1075) is mentioned, whereas the *real Tjemaras*, the *Cassuarina* spec. div. especially *equisetifolia*, is not mentioned; the whole series of *Waroe*, *Hibiscus*, spec. div. (Miq. I² 153), especially the *Waroe Goenoeng Heh. Vulpinus* neither. And we could cite more such instances.

THE SEYCHELLES ARCHIPELAGO.

REPORT BY U. S. A. CONSUL MUSSEY.

(Continued from p. 681, Vol. III.)

IMPORTS AND REVENUE.

The imports of the Seychelles consist of general merchandise, and the exports of coconuts, coconut oil, vanilla, cacao, coffee, cloves, nutmegs, fruits, vacuo bags, &c. The table appended gives the amount of customs dues received during the year 1881:—

Customs	$27,658 50
Licenses	8,448 50
Excise	6,841 50
Stamps	1,163 00
Taxes	11,863 50
Fines, forfeitures, and fees	6,315 00
Rent of Crown lands	513 00
Post Office	1,212 50
Miscellaneous	1,339 00
Total... ...	64,754 50

The country is poor, money is scarce, and, owing to the shrinkage in the production of coconut oil, revenue has been diminished, business has been arrested, and stringency in the money market has followed. As a natural sequence some time must elapse before an equilibrium can be restored, and if the disease which now infests the coconut trees and is fast killing them off will awaken planters to the necessity of putting in a variety of crops, instead of depending alone upon the product of the coconut tree for the support of themselves and their families, there is no reason why the revenue may not soon be swelled to its former proportions.

AGRICULTURE AND PRODUCTS.

Seychelles is favored with a climate admirably adapted to agricultural purposes; a soil strong and rich; and there appears no valid reason why its prosperity should be arrested, except by gross shiftlessness on the part of landowners, and a temporary scarcity of money. The influx of new blood with capital would soon raise the exports to a higher figure, and with increased exports come augmented imports and a greater volume of money.

The crops which grow specially well in Seychelles are vanilla, cacao, cloves, coffee, nutmegs, oranges, and lemons. The first named grows with great vigor and produces abundantly, and one planter has sold $17,000 of vanilla in one year from a plantation of ten acres. This season considerable new ground will come into bearing, and the exports of vanilla from Seychelles hereafter will be an item of some importance. The price of Seychelles vanilla in the Paris market ranges from $6 to $8 per pound.—*Indian Mercury.*

OUR INDIARUBBER SUPPLY.

The increase in the consumption of indiarubber in this country has been very large within the past ten years, and more particularly within the latter half of the decade. This is owing both to the great increase in the consumption of rubber boots, shoes and clothing consequent upon the increase in populating and to the multitude of new uses to which rubber has been put to the almost total exclusion of the horn.

Our imports of indiarubber are classed together with gutta percha, both being on the free list and being to some extent similar articles. They amounted to 21,646,320 pounds in the fiscal year ended June 30, 1883, and valued at $15,511,066. By far the larger portion was indiarubber. Our imports from Brazil alone footed up $8,600,000 in 1883, while we imported from Central America, United States of Columbia and other South American countries to the value of about $3,000,000, and African indiarubber imported for the most part via England foots up about $2,000,000.

The great bulk of our supply, however, and the best rubber also comes from Brazil, where its collection and preparation in crude state for shipments forms the principal resource of the two great provinces of the Amazon Valley, Pará and Amazon.

Next to coffee and sugar, rubber occupies third place in Brazilian exports. Notwithstanding this hardly any thought is given to the future of this great industry in Brazil. The same wasteful and exhaustive system of collecting the rubber which has been in vogue for half a century is followed today. The industry is chiefly in the hands of an uneducated and half-civilized nomad population of Indian mixture, and is pursued in a crude way with no thought beyond immediate profit. In consequence, millions of rubber trees have been destroyed, and many others abandoned from premature and excessive use.

The waste in this way is so great, that many well-informed Brazilians fear that unless better methods are employed, this rich resource will before many years suffer a serious and perhaps fatal decline. In the few cases where care is exercised in not tapping trees in the months of August and September, when they change their leaves, groves have yielded continuously for 30 years, and are still in good condition.

The rubber trees requires a growth of from 20 to 25 years before it produces the milky sap which forms the rubber. Hence little or nothing has been done to propagate the trees, and everything about the business is carried on as if the supply of trees would never give out. Brazil imposes a very heavy export tax on rubber, amounting, state and provincial, to 22 per cent from the province of Pará and 21 per cent from the province of Amazon.—*Boston Commercial Bulletin.*

BOLIVIAN CINCHONA FORESTS.

The great progress made in the acclimatisation of cinchona trees in India, Ceylon, and elsewhere, has awakened the Governments of countries where the plants are indigenous to the necessity of conserving from reckless destruction, and re-planting denuded forests, so as to be able to keep up the supply of this valuable product.

In Bolivia, since 1878, according to the report of the Netherlands Consul, private individuals and land owners have taken up the question with great earnestness, and at the present time on the banks of the Mapiri, in the department of La Paz, there are over a million of young trees growing.

New plantations have also sprung up in various other localities, either on private ground or that owned by Government. The competition of India and Ceylon in supplying the markets, has had also the effect of inducing more care in collecting and also of revisiting old spots, often with the result of a rich harvest of bark which had been left on partly denuded trunks, and the opening up of new localities. The new shoots springing up from the old stumps have yielded much quill bark, and the root bark of the old stumps has also been utilised.

The re-planting entails very little expense. The Indian tenant on an estate has a house and land from the owner (hacienda) of the estate. For this he binds himself to work for two to four days a week, at from 28 to 36 cents per day, women and children obtaining 16 to 21 cents per day. Thus the planting, weeding, &c., during the first two years, is but nominal in expense; after this period the trees may be left to themselves.

On Government land the expense is greater, as after an application being made, the land is put up to public auction, and may fetch a very low or a higher price, according to the bidding. The land secured, contracts are made with natives of the lower class to clear the forest and plant cinchona. The contracts are often sublet to Indians. The young plants are planted from five to six feet apart, with banana trees between, on account of their rapid growth and the shade the latter afford. From March to June, after the wet season is over, is the best time for planting, and the contractor keeps the plantation free from weeds and in good order for twelve months, when it is handed over to the owner. The following is given as the cost of the Mapiri river plantation of an area from 60 or more miles in extent:—

Ground	$1,200
300,000 plants at $0·14	42,000
Superintendent, buildings, &c.	4,400
Interest	4,800
Total...	$52,400

Till the plants are above two years of age, they are liable to die from drought or the attacks of ants, and during 1878 many thousands died from these causes. At the end of the fourth year some proprietors begin to collect the quill bark by the method of coppicing.

It is feared by some that should this new venture be successful, it will prove a dangerous rival to the plantations of India, Ceylon, and Java, and lower the price of bark considerably.—*Journal of the Society of Arts.*

THE POSITION OF SUMAC.

When the last crop of Sicily sumac was harvested it was found that the amount of prime quality available was much smaller than in previous years, and that while in the fall of 1882 there was a considerable surplus to be carried over, the opening of the crop season of 1883 found the markets nearly bare of supplies. The Continental buyers appeared to appreciate the situation, and made contracts for their probable requirements, thus leaving what was believed would prove a deficient supply for American consumers. The price was rapidly advanced, both in the primary market and here, as it was expected the supply would be entirely exhausted long before the crop of 1884 would become available, and up to $120 was at one time demanded for the best known brands. But from this point there has been a gradual decline until now supplies may be secured at $95. During this time of extraordinarily high prices the grinders of domestic pushed the claims of Virginia sumac to the attention of consumers, and as there is a wide difference in the price many consumers have used the domestic in instances where the Sicily at ordinary prices only had been used. This tended also to strengthen the position of the domestic, and the price was advanced to $75, and even $80 was paid in some instances. The consumption during the past six months, however, has been much smaller in this country than usual, and importers finding but little demand for their goods, they have gradually receded from their extreme views, although these were apparently warranted by the paucity of supplies, until the market finally reached $100, and latterly a further shrinkage to $95 has been brought about, all through lack of demand and the competition of importers to secure the little trade there was. It is now apparent that although the supply is very meagre, there need be no apprehension that the stocks will become entirely exhausted before the new crop will become available next fall. With an average consumption the last crop would probably have been entirely exhausted by this time, and prices would doubtless have been forced up to $150. Even with the present light demand, however, we need look for no further decline, as the supply yet available is small, although some of the shippers have latterly shown some anxiety to make contracts here at the prices now prevailing.

The high prices of the past six months has caused more attention to be directed to Virginia and other domestic sumac, and we are assured that the amount that will be harvested during the coming season will far exceed that gathered during any previous year. If the Sicily crop should again prove to be a small one, we have no doubt but that the grinders of domestic will realize a handsome profit, but the amount they will be able to dispose of is necessarily limited by reason of

its inferiority for some purposes. On the other hand, we have been assured that an improvement has been noticeable the past few years in the quality of the domestic product, and that the crops to be harvested this year will show a marked superiority over any previous crop. Even granting that this will prove to be the case, the conditions of soil and climate in this country are such that even with careful cultivation, which, owing to high cost of labor, is out of the question, the smmac produced contains an objectionable coloring principle, which no amount of care in experimental cultivation has heretofore eliminated. That an improvement may be or has been brought about we have no doubt, and we trust the industry may prove more successful than in years past, but the high prices of the past season may stimulate the business, so that it will be overdone, and the competition prevent remunerative prices from being realized.—*Independent Journal.*

SILK CULTURE—FOOD PLANTS.

MRS. M. J. G. HAMMACK.

There are hundreds of thousands of women who, being unable to do hard work, have no means of converting labor into capital, and to these silk culture is really the creation of a new industry. For the infirm, the invalid, and the child it is the open door to a competency, with no burden of drudgery. Let no one suppose that the cultivation of silk is a difficult pursuit, for it is a very simple one, and as instructive and interesting as profitable. There is no real obstacle to its success in America, for the dry and bracing atmosphere of this country is extremely healthy for the worms. One of the advantages of the silk industry is that a comparatively small amount of capital will yield a large income, so that to a person with limited means and a family of children, the culture of silk holds out encouragements of extraordinary promise. Women and children can make one hundred dollars the first year after planting the trees, and the second, from one hundred and fifty to three hundred dollars, with one acre of mulberry trees.

The gathering of the leaves and feeding the worms may be done by the children, one adult person always directing the business. It should be borne in mind that in silk culture the brain is of more importance than the hand. The first important step is to prepare the proper food for the silkworm. The leaf of the mulberry is the best, and this tree will grow and the silkworm thrive upon it throughout the United States. The maclura or osage orange is a substitute for the mulberry, and a fair crop of silk can be raised from it, but any one hoping for complete success in its use may become discouraged. The danger in handling the thorny osage, the difficulty in securing sufficient leaves on account of the thorns, the danger of the succulent leaf at the last stage of the worm, and the great care to be observed in not using the upper end of the shoots, should prevent any one from relying entirely upon the osage as principal food. It will answer to experiment with while the mulberry trees are growing, but to use osage entirely doubles the expense both in gathering leaves and using the branches. Worms fed on branches are the most healthy, as that is their natural way of living, and they enjoy creeping about on the twigs. The mulberry will ever retain its superiority as a reliable and continuous food for the certainty of yielding an unexceptionable quality of silk, and its vigorous growth and production of suitable foliage invest it with properties not combined in any other plant. One-year-old trees can be used to make a crop of silk, and where the plants are set out close together as for a hedge, the clipping of the twigs and branches will favor the growth of numerous shoots which will become valuable leaf-bearing branches the next season.

For standard trees they should be set out twelve feet apart each way, and in this mode of cultivation the trees interfere but little, if any, with the use of the land for other purposes. Corn and small fruits may be grown between the rows of trees. Planting in hedge rows is the most approved mode of cultivation for convenience in gathering the leaves.

The Moretti mulberry is profitably grown for a hedge, as the large size of its leaves make a very desirable variety. The Italian mulberry is generally preferred to all other kinds. It grows rapidly, and is clothed with leaves fifteen or twenty days earlier than the other varieties. The Russian mulberry has taken a very prominent place, and owing to its hardiness and rapid growth is in great demand; it produces fine, strong silk. The trees make excellent timber and are prolific fruit-bearers. The aromatic and juicy berries are often more than an inch long, one half inch in diameter, and vary in color, from jet black to light red. The fine fruit more than pays for the labor and expense of growing these trees. All the varieties of mulberry trees mentioned are hardy, grow rapidly, attain a height of twenty or thirty feet, and make beautiful shade trees.—*American Agriculturist.*

ECONOMIC PLANTS IN TENERIFFE.

Reporting on the trade of Teneriffe, the British Consul makes some remarks on the agricultural capabilities of the island, from which the following notes are taken. He remarks that it is a matter of some surprise that, notwithstanding the mild nature of this climate, its even temperature throughout the year, the absence of all sharp frosts and scorching heats, and where everything almost might be made to grow, and living rendered cheap, only about one-seventh of the land is under cultivation. The crops of Wheat, Barley, and Indian Corn raised are insufficient for the wants of the country, and large quantities of the first necessaries of life are derived from abroad. Many kinds of fruit are cultivated, but with the exception of Bananas, which are mostly shipped for Spain, and Prickly Pears, the fruit of the Tuna, or Nopal Cactus (Opuntia Tuna), which are the principal food of the labouring classes in summer-time, and also perhaps Figs, the different varieties, abundance, and quality, are far inferior to those of Malta or Sicily.

Orange trees and Apple trees, although thriving well all over the island, seem to be attacked by blight, or oïdium in some districts after the flowering and before the fruit comes to maturity, nevertheless good Oranges are plentiful.

The Caña dulce (Sugar-cane), Tobacco, and Coffee, also grow easily and yield returns, but they do not as yet hold out much prospect of becoming articles of export competition, and the expensiveness of the manufacturing process of sugar being the chief obstacle to the production of this article; but, notwithstanding the drawbacks, considerable quantities of the plant in the stalk of about 5 to 6 feet long were imported last year from Madeira, Grand Canary, and La Palma, and planted in this island with much success. As regards Tobacco, considering that the plant does not call for much care or attention in its cultivation, and only requires water at long intervals, it would no doubt be more extensively grown if only inducements were held out to farmers by the authorities.

The Coffee plantations at Salamanca consist of about 200 or 300 trees each; although bearing abundant fruit, the yield is chiefly consumed by the growers themselves. The Coffee is of excellent quality, and there is no reason why this plant should not also be more extensively propagated. The climate and soil seem very suitable to its growth, especially when protected by the shade of other trees, when it will throw out horizontal lateral branches throughout its entire length, and in the early part of the year the branches are literally covered with fruit.

The greatest anxiety of all, however, is the discovery, if possible, of some vegetable product which will replace the Tuna or Cochineal Cactus. In view of this consideration, which is still occupying public attention, the Real Sociedad Economica de Amigos del Paris de Tenerife, the Royal Agricultural Society at Laguna has for some time past been in active correspondence with friends in England, who have suggested the introduction into this island of fibre-yielding Nettles, especially the Rhea or China grass, and the Helianthus annuus (Sunflower), but on this point Mr. Consul Depuis says:—"Whether any advantage will be taken of the many valuable suggestions made I am unable to say. I have very little doubt, however, in my own mind that the climate and conditions of this land would admirably suit those plants, requiring as they do little cultivation and thriving in almost any soil. The Helianthus is a well-known plant here, and I have seen magnificent specimens of them cultivated as ornamental plants. In short, since the unfortunate failure of the Cochineal as a remunerative product, the only agricultural resources remaining to this island for exportation seem now to be Potatoes, Onions, and Garlic."—*Gardeners' Chronicle.*

AGRICULTURE ON THE CONTINENT OF EUROPE.

(Special Letter.)

Paris, August 9th.

The harvest may be considered as terminated in France. Wheat will be an excellent crop, despite the run of tropical weather for the grain. Oats and barley will suffer a little, except on the sea-coast or in humid situations. Green crops can yet pull up. As for forage, it will be defective. But this prospect has been anticipated by maize sowings for *ensilage*. A farmer then has only himself to blame if he be caught like the foolish virgins with no oil in his lamp.

The summer has been very warm and dry, but on the whole cannot be described as drought. And this leads me to the subject of green manuring, which is steadily making way in the warm zones of France, and on light soils thus resenting all the conditions of success. A plant which borrows from the soil to grow, repays, when ploughed in, capital and interest in dying and decomposing on the spot. This is the reason why lands are laid down in grass to grow rich. The organic manure that we bury in the soil contains soluble and insoluble matters, the latter predominating. The first can serve to immediately feed the plant and be assimilated; but for the second, they must undergo fermentation to dissolve their parts or elements, and so give place to the production of new soluble compounds and gases. No food can reach the plant except in a state of extreme division, as the absorbing pores of the little roots are so delicately fine as to take up liquids or gases.

It is under the triple influence of heat, air and humidity that the decomposition of organic matter takes place in the soil. Green or vegetable are evidently cold manures. Their action is slow and their decomposition difficult: they contain too small a quantity of saline matters, or saline matters of an insoluble character, or they may be of a too aqueous nature. The character of the soil has a good deal to do with respect to the action of vegetable manures. In sandy soils the decomposition is more rapid, because the air and the agents of decay have freer access, while, in the case of clays, decomposition proceeds more slowly, as their tenacity excludes air and heat. The humus in a clay soil is hastened in its decay by tillage, which opens it to the influences of the atmosphere. For similar reason, if a sandy soil be tilled too frequently, the manures become rapidly soluble and volatilize in the air before the plant can profitably utilize them.

The ploughing-down of green crops before arriving at maturity, is, perhaps, the earliest form of manuring land, and may be also the last. It is a precious auxiliary in localities where roads do not exist for carting farmyard manure, or are impracticable, as on mountain slopes. Rape, aftermaths, lupins, buckwheat, rye, beans and turnips are the plants chiefly employed in green manuring. The Germans, and they are right, patronize two, a mixture, as turnips and spurry. The more rapidly such plants grow and develop plenty of leaves the better. Before being ploughed in, they are rolled or mown. When in flower is the best time to utilize such plants; they are richer too in alkalies, as Dr. Sace points out, that is the period selected by fabricants of vegetable ashes for cutting. In Belgium, the weeds of the cereals are cut in spring and carted to land prepared for potatoes; drills are opened four inches deep, the seed dropped and the green weeds spread over it, the whole being covered with the hoe. This manuring does not tell on any subsequent crops.

In Bretagne and the north-west of France rushes and heather are employed; these are generally strewn first on a road to be bruised by the traffic. In the Upper Pyrenees lupin is sown in autumn, and in May, when in flower, is ploughed in; this forms an excellent preparation for maize. In Sarn-et-Garonne sainfoin is sown in the vineyards and ploughed down; on light soils vetches and buckwheat are in favour, and seems to be preferred of late on the calcareous lands of Champagne. The Prussian farmers prefer yellow lupin, the Belgians learn to spurry and adopt the excellent plan of spreading a little farmyard manure and covering both simultaneously. In the Luxembourg the slopes of Erézé have been made arable by green manurings five years in succession. At best, ploughing down green plants can be only half-manuring. The plan possesses the undoubted advantage of maintaining humidity in the soil, and when the latter is of a calcareous, sandy, granitic or schistose character, such is not to be overlooked. Green manuring never affects the flavour of products nor removes anything from their delicacy.

Beet pulp obtained by the diffusion process of sugar extraction contains only 5 per cent of dry matter; mechanical pressure can augment this to 15 per cent. Impossible to exceed the latter figure, as the water is retained in the cellulose membrane other than in a mechanical form. Professor Maercker, by adding a half per cent of a solution of lime, and then pressing the pulp, has obtained 35 per cent of dry matter. The lime does not affect either the animals or the pulp. The importance of this discovery is very important in the ensilaging of beet pulp.

A German naturalist draws attention to the fact, that all poultry kept in yards will, if of a dark or sombre plumage, be better layers than those of bright colour. Black absorbs more heat and maintains greater vital warmth. White geese and ducks are not reputed good layers.

M. Boitel, who has devoted much attention to pasture-lands, asserts we ought to study to ameliorate the varieties of grasses peculiar to a locality rather than to the introduction of foreign kinds. The Perche meadows thus prepared surpass all others.

JAMAICA, ITS ORCHIDS, &c.

One of the principal drives across the island of Jamaica is by the Bog Walk, and starts from Spanish Town, the ancient capital of the island, to St. Ann's Bay on the north side. Three-quarters of an hour in a train takes one from Kingston to Spanish Town where one finds a post-office omnibus drawn by three mules abreast to take one to St. Ann's Bay, a distance of 48 miles. There are three changes of mules on the way and the trap is pretty comfortable. The fences for the first five miles are made entirely of Pinguins (Bromelia Pinguin), and are absolutely impenetrable to the most enthusiastic Orchid hunter, though the bright flowers of Broughtonia sanguinea are to be seen everywhere on the trees; then one comes to the beautiful Bog Walk, which is to be seen in perfection under a full moon, with a Sambo girl whispering its praises in one's ear. It is needless to say that I did not see it in perfection, but I saw it under the full rays of a bright sun tempered by a nice sea breeze. A witty governor of Jamaica about thirty years ago summed up the three delicacies of the island as being the black crab, the mountain mullet, and the Sambo girl. Two of these I can answer for, but the third and last remains inexperienced. The river flows swiftly close by the side of the road, its waters clear as crystal and the mountain mullet darting about. One crosses the stream by bridges which, when the river is high, are very often uncrossable. The tropical vegetation on either side of the road is magnificent, and on every spare space of soil now is planted the Banana.

This pass continues for about five miles, and the road ascends to the top of the backbone of the island. The stone walls which take the place of the Pinguins for hedges are covered with Epidendrums fragrans and cochleatum. They grow everywhere on the banks of the walls, on the walls, and on the trees, and intermixed is a small Ophrys with pretty spikes of purple flowers. Phaius grandifolius or Bletia Tankervilliæ is also very common, and is generally distributed over the island, though I cannot understand how it came here, as it is a native of Hongkong. After St. Ann's Bay the Orchids ceased and I could not find one of any tribe in a month's stay on the north side of the island. At the King's House, the residence of the Governor, there is a nice collection of Orchids under cultivation. Dendrobium Pierardi latifolium has stems full 7 feet long, and one mass of bloom; Dendrobiums nobile and tortile are also doing nicely, but the masses of Oncidium ampliatum majus surpass anything that I have seen in this country. Amongst others Oncidiums flexuosum, sphacelatum, altissimum, Papilio, and Krameri; Cattleyas Mossiæ, Skinneri, and Trianæ; Aërides odoratum, Epidendrum fragrans and prismatocarpum; Gongoras in quantities, and Mormodes and several Zygopetalums, were all doing well, but curious to relate, there was not in the island, that I saw, a healthy plant of Peristeria elata; although it comes from the mainland so near, and is planted under the same natural circumstances as it grows under at home, yet it does not thrive in Jamaica.

At Mr. Morresco's house about three miles from King's House, there is a collection of about the same size and containing very much the same plants as I have mentioned, but he has also Dendrobium macrophyllum giganteum doing excellently. Mr. Morresco is a genuine lover of Orchids, and means importing and trying to acclimatise a great many more genera of Orchids than we have yet seen in Jamaica.

The island on the whole is in a bad way: labour is scarce on account of the emigration of the nigger to the Panama Canal, but that will soon right itself. Sugar is down and going down; rum is not paying well; but fortunately for the landowners on the north side of the island an enormous trade has sprung up with the United States in Bananas. The Cocoa-nuts are still exported in great quantities, and the demand for them increases in the States rather than diminishes, so that each Cocoa Palm is said to be worth a dollar a year, and if it grows near one of the small but excellent harbours of the island, it undoubtedly is worth a dollar a year. A retired M. D. had some land left him near Annotto Bay, he added on to the property by purchase, and without any idea of gain, but merely for their beauty, began planting Cocoa Palms. Now he is one of the richest men on the island. When taking stock of his Palms he is said to have lost count at 130,000, but I will not guarantee the truth of the number; however, the whole of his land is covered with palms. Coasting schooners carry on the trade with the mainland in Cocoa-nuts, and they take them with their outer husks on, and they give 5s. per 100 for them delivered on the beach.

But for the more perishable Banana fast crew steamers are employed, fitted up in their holds like cellars with bins and stroog air pumps for refrigerating purposes. The "Banana King," as an ex-captain of a small trading schooner has been nicknamed, resides at Port Antonio; he began life as a seaman, and rose to be captain of his own schooner. His first attempt in the Banana trade was made about ten years ago, when he carried some sixty bunches to Charleston, and found it a profitable trade. He commenced then to buy up every bit of land he could near Port Antonio, and planted Bananas; gradually he bought screw steamers, and now he is buying up all the land near Morant Bay and Port Morant, where he is also planting Bananas. When he has not sufficient Bananas of his own to fill one of his steamers, he scours the country round to buy up those of his poorer neighbours, and one day that I was with him he was giving from 2s 6d. to 3s. a bunch to make up a cargo. The profits in this trade amount to about 50 per cent on the capital employed, when you own your own steamers and have your own Banana plantations. The Banana bears the second year, and requires very little in its cultivation, and consequently entails very little expense. A large trade is also springing up in Oranges, now that care has been exercised in selecting the right varieties.

The Orange tree flourishes best in the higher parts of the island, from an elevation of 1,500—2,500 feet; formerly they would not bear export from the rough way in which they were handled and packed, but now, from the great care employed, Jamaica oranges can compete with those from Florida in any of the great centres of the State; they are of the most delicious flavour, and very large in size. Limes grow everywhere in the island up to an altitude of 2,000 feet, and Shaddocks do also very well. The climate of the north side of the island is charming—to my mind the most charming in the world; a deliciously cool sea-breeze springs up about 8 a.m., and blows until 4 p.m., when there is a lull, and about 8 p.m. a softer land breeze begins to blow and lasts until 4 a.m. Stephanotis blooms most luxuriantly, and Marechal Niel Roses attain to a size and colour and substance of blossom unequalled anywhere. I cut one morning seventy blossoms from a three-year-old plant—any one of which would have been a prize winner at a London Rose Show. Tea Roses, such as Niphetos, Homer, &c., also do equally well. Yams and other vegetables a rich planter does not find it worth his while to cultivate, and he buys them all from his negro cottagers, and there is no attempt at a regular kitchen garden throughout the island.

The hotel accommodation throughout is very bad, and there would be an excellent opening for British capital in this line, particularly as the Canadians and some of the Northern Americans have taken to spending the winter in the island, and avoiding the rigours of the American season. Some of the beauties of Jamaica, in the way of waterfalls and lovely natural dells, I have passed over; but any one going out there can easily make themselves acquainted with them from the excellent handbook of the island published under the authority of the Government.—E. W. Walker.—*Gardeners' Chronicle.*

THE INFLUENCE OF FORESTS ON CLIMATE.

The advantages attending the conservation of forests and the benefits to be derived from the re-afforesting of denuded lands are subjects that annually, when the season for planting arrives, excite a considerable amount of agitation, the result of which has been, so far, much talking and writing, but very little action. It needs no argument to prove that the better a country is wooded the greater is its value in an economical sense, and it would be difficult to fix a limit at which tree planting should stop, especially in a country like Australia, where, in some parts, timber is naturally scarce, while, in nearly all parts, it is rapidly becoming still more scarce, through the devastating action of human beings, forced on by the needs of a high civilisation. There can be no difference of opinion as to the wisdom of economy in the use of timbered land or of maintaining its existence in a progressive state, but the advocates of tree conservation and tree planting are apt to claim too much for forests, and in addition to their commercial value, rank them as the chief or almost the sole regulators of climate and rainfall. As evidence in favor of their views they bring forward the cases of Palestine, Mexico and other countries, once the seats of teeming populations, and where agriculture was carried on in the greatest perfection, which are now little better than deserts, owing, as they say, to the denudation of forest lands and consequent lessening of the rainfall, but a careful study of history dispels the illusion by showing that such is not the fact. The decrease of population and the destruction of the works of ages of civilisation were the acts of conquering hordes of barbarians in both the cases quoted, as well as in Peru, the north of Africa and other parts of the earth. At the present time the annual rainfall at Jerusalem is 61 inches, very much greater than the average of Victoria, and nearly double that of some parts of this country where agriculture is carried on with advantage, and though Palestine may be considered comparatively barren, it is quite capable of being again rendered "a land flowing with milk and honey," were it freed from the misgovernment of its oppressors. The same causes have produced similar results in Mexico and Peru, where, from the ostensible desire to Christianise the inhabitants who have been more than decimated, and the land reduced to the condition in which it is found today. It is frequently put forward that the rainfall of the country is declining, but that is a hazardous assertion, for a long series of years of measurement is required to enable any one to speak with certainty on that point; and, indeed, a large amount of evidence to the contrary might be brought forward. Mr. Russell, Government Astronomer of New South Wales, has stated, from actual observation, that "the years 1799-1800 and 1801 were three dry years in succession, as were 1818-1819 and 1820. That Lake George, which in 1820 was a magnificent sheet of water, was then said by the aborigines to have been seen dry; in 1824 it was 20 miles long and 8 miles wide, and was found by Sir Thomas Mitchell in 1836 to be a grassy meadow with dead timber on it; to become subsequently a sheep and cattle run, and to be again in 1874 a greater lake than ever." And the conclusions arrived at by Mr. Russell and others are that timber is the result of rainfall and conditions of soil. It is not a cause of rainfall. That in those countries where the forests have been more largely cleared, as Australia, Canada, and the United States, the climate has not been affected thereby. That in Australia two conditions affect rainfall, namely, distance from the coast and altitude, and that these conditions are true, no matter whether applied to plains or timbered land. Mr. Ellery, our Government Astronomer, in a paper on the influence of forests on rainfall, read before the Royal Society of Victoria, remarks that "the full significance of this question only presses on the public mind at times of drought and water famine; it has, however, occupied the attention of

scientific men in most countries as a great climatic problem for a long time past. In some instances a partial solution has been reached, apprising the people that such and such deplorable changes of climate were the inevitable and natural result of artificial changes of the earth's surface, which had been going on for centuries, and which would take a long time to restore to its pristine and genial condition." Further on he says:—"Experience, however, supplies us with one or two important facts, first among which is that no marked diminution of average annual rainfall over any extensive region can be traced solely to the denuding the earthy surface of forests, although the local effects of such a proceeding are usually well marked." Not that the average rainfall is less than it would otherwise be, but that it is made up by excessive falls at one portion of the year, or at isolated times, with excessive dryness and scarcity of water as the normal condition. But though forests produce little or no effect on the average rainfall of large tracts of country, their presence or absence does make some difference in regard to its distribution and consequently to the fertility of the land. Forests are conservators of the rain that falls, a shower of rain falling upon the trees of a forest is, in part, retained for a time on the foliage and bark of the trees, and of that which falls to the ground, a large portion is absorbed by the living and dead vegetable matter on the surface, evaporation is diminished and the moisture is allowed to quietly sink into the soil, instead of rushing off in floods, and from its gradual accumulation giving rise to springs and rivulets, and equalising the flow of streams and rivers.

In an article in the *Indian Forester*, by Surgeon-General Balfour, on the influence of trees on the climate and productiveness of the peninsula of India, some valuable tables are given showing that the total amount of actual rainfall has not diminished of late years, but that man, by denuding the land of forests, is allowing the rain water to rush off the surface, sweeping away with it the mould, breaking down the tank dams, starving the springs and draining off the waters of the springs, rivulets and wells. The rainfall, repeats Mr. Balfour, has not diminished, "but man, partly ignorant and wholly reckless, has denuded the soil of its trees and shrubs and bared the surface to the sun's rays, thus depriving the country of its conservative agents and making the extremes of floods and droughts of more frequent occurrence and more severe." "Storms," says a French writer—M. Fautrat—"are rare in wooded countries, the electricity of the air being gradually drawn of instead of accumulating. Hail especially is rare where there are many trees. M. Cantegoil has tracked many of the hail storms so destructive in France, and has found that they generally make a leap over a forest. Early in June 1874, for instance, a hail storm which had swept over the department of Ariege entered that of Ande. As soon as it got to the forest land, the hail totally ceased; but when it reached the treeless department of the Eastern Pyrenees, it began again with great fury; yet there was electricity enough in the air over the forests, for several fir trees were struck and shivered to pieces. But hail is caused by the very rapid evaporation of rain passing through an exceedingly dry stratum of air. Evaporation, we know, always causes cold—this is the principle of water coolers, &c.—and in this case the latent heat of the rain is withdrawn so rapidly that the result is frozen rain drops. Hence, in wooded countries, where the air is always moist, the evaporation is slower and rain falls instead of hail." Thus, forests produce various effects on climate and rainfall. There is the chemical action of their leaves, which decompose the carbonic acid of the air, fixing the carbon in their woody tissue and liberating the oxygen. There is their physical action in hindering evaporation and stopping currents of air and in covering the ground with a vegetable mould which holds water like a sponge. And there is the organic action of the leaves which, in breathing, restores to the air a part of the water which the roots have drained from the soil. Lastly, there is the mechanical action of the roots, which at once prevent the earth from being washed away by rain, and also enable the water to filter down deep into the ground. Forests, then, ought to make a country cooler, by withdrawing the carbon from the air; the heat that is set free when wood is burned is the very heat that was being absorbed while it was growing. A forest may be looked on as a vast condensing apparatus for storing up the heat of the stmosphere. That is what theory says, and experiment confirms it. The mean temperature of a wooded country is always lower than that of a similarly situated treeless country; but—and this is important—the cold is less extreme, as well as the heat, and changes of temperature are gradual. In addition, forests arrest and destroy miasmata, rendering their site and neighbourhood healthy; they set a limit to the spreading of the spores of rust and other fungi from cornfields and orchards; their humid atmosphere, shade, and the feathered inhabitants they encourage effectually obstruct the march of locusts and other destructive insects, while affording sustenance to and promoting the increase of the honey bee. Forests also benefit mankind by increasing the fertility of the soil, decomposing the rocks by the penetration and chemical action of their roots, and adding to the surface soil the mineral elements of vegetable nutrition. In various parts of the globe sterility has been caused by the destruction of forests on hills and sloping grounds allowing the floods to wash away the surface soil to such an extent as to produce complete sterility, and the same may happen here if means are not adopted in time to prevent so fatal an occurrence by keeping the soil firmly bound by the roots of trees and other vegetation, for indeed the destruction has already begun and may be witnessed, on a small scale as yet, in various places A great deal requires to be done also in stopping and preventing the encroachment of the sands of the sea, and which nothing but planting can thoroughly effect. Let the legislature then no longer dilly-dally with the subject, but make enactments whereby conservation of both young and mature timber, and re-afforesting of denuded ground, may be carried out on a scale commensurate with its importance.—*Leader*.

The Mayall Rubber Company's factory at Reading, Mass., was burned on Monday morning, nothing but the engine room being saved. The building was a large one-story brick structure, about 250 feet long. It had been erected about three years. The company manufactured rubber goods of all descriptions. The factory had not been running on full time lately. A large drying room had just been finished, and the company were intending to run on full time. There was a large stock of rubber on hand. The loss is estimated at from $175,000 to $200,000, partly covered by insurance. About 100 persons were employed in the factory.—*Independent Journal*.

Various substances have been used to make stoppers for bottles that will replace corks, and paper has formed the basis of many of these. We now have a more novel use of paper in the drug business in the form of paper bottles. The difficulty of making them waterproof has been overcome, as well as their tendency to be affected by spirits of any kind. The only difficulty that remains is that they must be made in halves, and be joined together after taken from the moulds where they have been enduring a severe pressure, and where the albumen of some of the ingredients has formed an impenetrable protection, and it only requires that some deserving mechanic eliminate a pulpy alloy that can be used as a solder.—*Ibid*.

Salt as a Fertilizer in the Orchard.—"A. W. Langdon," Erie Co., N. Y., asks our advice "as to the quantity of salts advisable to use about fruit trees in a old orchard." There is no more positive knowledge as to the value of salt as a fertilizer for fruit trees then there is regarding its utility when applied to field crops. The fruit trees to which it appears to have been most beneficial are the plum and quince, and on these it has been used more as a remedy for diseases than as a fertilizer in the proper sense of the term. Salt in sufficient quantity applied to the roots will destroy all vegetation, including the largest trees, hence caution must be exercised. Mr. Meech, the successful quince grower of New Jersey, advises a pint to be applied to the soil around quince trees that are two or three years old. Whether salt will produce a better effect upon old orchard trees than a good dressing of fine bone we much doubt. If applied to old orchard trees we should prefer to try two quarts, sprinkled upon the soil as far as the roots extend to a larger quantity. We hope Mr. L. will try the salt, and also upon some of the other trees, a liberal dressing of ashes, of bone flour and stable manure, and report the comparative results.—*American Agriculturist*

THE JUTE TRADE OF CALCUTTA.

Calcutta, 23rd August.—At the present moment when the value of the shares in all our Jute Mill Companies has been so seriously depreciated, a few words on the jute manufacturing industry in India may not be out of place.

Few of our readers are, we imagine, aware of the amount of capital invested and the number of persons interested in jute mills here. Many of them have been erected quietly, and most of them have been increased or added to from time to time, so that at the beginning of this year there were 20 jute mills at work, containing just 6,000 looms, while during the present year some 1,000 additional looms must have been set up, all adding to the production and tending to keep down the price of the manufactured article. Now the cost of a jute mill, if we may judge from the published accounts, varies from R4,500 to over R6,000 per loom, so that if we take the mills all round as averaging in cost 5,000 per loom, it follows that the capital invested in these undertakings cannot be less than 3½ crores of rupees. We are inclined to believe that when all the extensions now in contemplation are completed, the invested capital will be nearer five than four crores of rupees. The number of persons engaged in a jute mill works is nearly 10 per running loom, so that we may take it that at the present moment some 70,000 hands are engaged in these mills, quite independently of the number who are indirectly supported thereby. The jute manufacturing industry in India seems to work in cycles of alternate depression and extreme prosperity. Up to the year 1874 the manufacture was almost a close borough here; there were not above six mills at work, with a total number of certainly not more than 1,500 looms, and the trade was conducted with very great profit to all concerned. The year 1873, however, saw a very great impetus given to the erection of jute mills, and in that year and 1874 at least 10 new concerns were floated. With the commencement of 1875 came the first great crisis in this industry—the supply overtook the demand, prices for the manufactured article receded, the large profits of former years dwindled down in many instances to losses, and shares in Jute Mill Companies went to a serious discount. This state of things continued, with some little fluctuations, until about the middle of 1880, and during the interval several concerns had a uncommonly bad time. The Balliaghatta, Rustomjee, Calcutta, and Oriental Companies, with a combined capital of some 44 lakhs of rupees, succumbed, and have been liquidated, the return to the shareholders having been infinitesimal; while shares in nearly every other company went to a serious discount, varying from 10 to 85 per cent. The pressure on the mills became at last so serious that they were compelled to seek foreign markets, and Australia, New Zealand, South Africa, California, and Valparaiso were successfully invaded, and after a hard struggle wrested from Dundee. Indeed the depression in trade became so great that in 1878-79 and the early part of 1880 large quantities of gunny bags were shipped from Calcutta to the United Kingdom and the mills here met the Dundee spinners upon what had hitherto been considered peculiarly the latter's ground.

In 1880 an impetus was given to the gunny bag trade by Mr. Plimsoll's Bill, while the largely increased shipments of grains and oilseeds from India within the last few years have caused a greater demand for bags; so that the year 1881, 1882, 1883 have proved very profitable ones to jute manufacturers both in Bengal and Dundee. Unfortunately this improvement in trade was at once seized upon by many of the managing agents—who saw therein a considerable increase to their emoluments—as an excuse for considerable extensions; while one or two mercantile firms, with a handsome commission in prospective, issued circulars to confiding investors, wherein were depicted in the most glowing terms the large profits to be made in the jute manufacturing industry. The result might have been anticipated. On the 1st January 1881 some 4,600 looms only were at work in India; but three mills, which were then silent, are now at full work, and additions have been made to other concerns, so that on the 1st January 1884 the number of looms at work amounted to 6,000, while some 2,200 more looms were under construction, of which we expect some 1,000 are now at work. In other words, the manufacturing capacity has been increased fully 50 per (cent during the last three years, and there are further extensions in progress, so that the question to be seriously considered is, what is to become of the out turn of the mills?

The years 1882 and 1883 were rendered more profitable than usual to the localmills by reason of the extremely large crops of jute in 1881 and 1882. Prices of gunny bags were most moderate while the mills were enabled to make a very handsome profit on the manufacture; in fact, everything worked to put money into the pockets of these who brought their jute and sold their bags with judgment. There is no doubt that the gunny bag trade is an expanding one, but there are reasonable limits to everything, and signs are not wanting to show that at present the supply has overtaken the demand. Thus in 1879, 68 million bags were exported by sea from Calcutta, and 67 millions in 1880. In 1881 the number rose to 74 millions; in 1882 to 81½ millions, and in 1883 to nearly 91 millions. But the exports for the first half of this year are only 4 per cent above those of last year; and it is noteworthy that the increase in one year over the other has almost invariably taken place during the first six months of the year. It is evident that the increase in production this year will be considerably more than 4 per cent. Again enormous numbers of bags are required for the ordinary export trade of the country; for the three months, April to June 1884, the exports of grain and oil seeds were some 295,000 tons less than for the corresponding period of 1883. This means that nearly eight million gunny bags were not required this year, which were used in 1883. At the present moment the Calcutta share market, so far as regards jute mill scrip, is completely demoralized, and the depreciation of this particular kind of stock has been something terrible. The causes of this reaction may be shortly stated as dear jute, dear money, and over speculation by weak holders.

But though the jute manufacturing industry is at present depressed, and though the immediate prospect of dividends is unlikely, there is no class of industry in which we have a more thorough belief, or which stands on a firmer basis. It must not be forgotten that hitherto Bengal is the only place from which jute can be obtained, and that therefore to place the seat of the manufacture here was to secure for it advantages which no other country could afford.

It is extremely satisfactory to observe that the second half of this year has opened well, and that the exports of gunny bags during July are greater than have been known before; and if this only continues, 1884 will show as large an increase over 1883, as that year has over 1882. The extreme cheapness of gunny bags has caused a strong demand for them in the Straits, and if they can only succeed in ousting the mat bag at present in vogue in Siam and China, there will be a grand outlet for our bags: but it must not be forgotten that this unexpected demand has been caused by the usually low prices obtaining for the manufactured article, and that had it not been for this sudden spurt at the Straits, our export figures would have looked very different.

It is noteworthy that, in consequence of the low price of jute last year, though the number of bags exported was fully 17 per cent more than in 1882, their value was almost the same, and it evidences the severe character of the present depression, that with jute this year at a considerably higher range of prices, the value of bags has not at all increased. At the present moment well-managed mills, with no large stock of dearly bought jute, should be able to work at a small profit, and the extreme depression in some of our jute milk shares would hardly seem to be warranted. The future of the jute manufacturing industry here is largely bound up in the question of railways. Extend the railway system and you increase the export of agricultural produce and *ex necessitate rei* the demand for gunny bags. There seems now to be every probability of a great impetus being given to the construction of railways; this is the best news that the mills have had for some time. Investors in the stocks of well-managed mills at present prices may have to play a waiting game, but the ultimate results should more than compensate them for their forbearance.

It should not be overlooked, that the share market in the beginning of 1880 was in quite as bad a state as it is now; yet since then we have had nearly three years of very good trade and very large profits.—*Pioneer.*

PLANTING MATTERS IN CEYLON.

The coffee industry appears to have as many lives as the proverbial cat. Three crises in its history have been distinctly marked, and now there are signs of a revival—not in price, for that is low enough, but in condition of the trees, the coffee pest notwithstanding. The seasons may have a good deal to do with it, and surely we have not had such a rainless south-west monsoon as the present for many a long year. It has been breezy enough, but the rainfall has been abnormally light,—no bursts, no heavy downpours, only occasional showers, just enough to keep the tea refreshed, but not nearly enough for planting out.

There will be comparatively little tea put out this season, and, as a matter of course, the bushes will not flush as they should, and the shipments will show a decrease. Still there is a large area of new and old land out in tea, nobody can say how much; but go where you will, even amongst really good coffee, you will find young tea coming in. We went a long round a short time ago through some of our once most favoured coffee districts—north, east and south, and in every direction there were the same signs of transformation, the conversion of the old coffee estate to a young tea plantation. At first it was believed that the old land on which coffee had thriven and borne crops for so many years—thirty and forty in some cases—would not grow tea—but this has now been proved a fallacy—at any rate for some years tea has flushed on such land, and crops of 400 lb. per acre are being taken off many an old place that had long ceased to be productive in coffee.

In the course of our journey we passed through estates that in their palmy days had given coffee crops of twelve and fifteen cwt. an acre, now all but refusing to bear, yet growing tea vigorously and of excellent quality. The object of our journey was to gather information as to an insect pest which is said to be attacking *cacao* trees in bearing. We do not mean the coconut trees which are palms, growing only in the lowcountry, but the tree now being extensively cultivated in various parts of the interior of the island, and from which the chocolate bean is obtained. Recently numbers of these trees have been found dying at the branches, which are eaten round the edges,—at the same time that the fruit pods are perforated by some insect, and the only creature found on and about the tree is the *Helopeltis Antonii*, known on Indian tea estates as the "musquito blight." These tiny things are invisible during the day making their appearance only at night; and where they harbour at other times no one has yet discovered. We visited three *cacao* estates; and true enough on one of these there were visible signs of the work of some insect pest, though the little destroyers were not to be seen; but they had done a good deal of damage, causing the loss of an entire crop then coming forward.

On the other two estates visited, we did not feel satisfied that the sickly appearance of the trees had been caused by any living creature, but was rather the consequence of the extremely dry weather acting on a somewhat shallow soil; it is well known that this tree cannot stand drought, especially if the soil be poor and not of any depth. Opinions amongst planters are divided as to the existence of any insect pest as the cause of damage; but so serious is the matter thought to be that the Government has been requested to depute Dr. Trimen, their botanical adviser, to investigate the affair, whilst the Planters' Association of Kandy has named a committee of its members to institute enquiries and carry on investigations on the subject. There is very grave apprehension with regard to the existence in our midst of the *Helopeltis*; for if it be really existing and doing damage to the *cacao*, it will be impossible to say when it may not attack our newly-formed tea plantations on which the hopes of the planting community are now centred. This same insect exists in great numbers in Java, but there, strange to say, it attacks only the cinchona, never troubling the tea,* so that gardens may not after all suffer much from it.

There is in Ceylon not only a Central Planters' Association in Kandy, but branch institutions in various planting districts, where local subjects are dealt with, as well as questions affecting cultivation; the largest measures of the day connected with Government action in planting matters, are usually taken up by the parent institution of which the others are the offshoots.

One result of this Co-operative Association is that the most reliable information is obtained concerning the progress of cultivation throughout the island, nothing being left to guess-work. Everything connected with the coffee, tea, cinchona and *cacao* interests is in the possession of the Association, all of which is made public in the Ceylon Estates Directory † and the proceedings of the body, printed yearly. The only information dwellers in Ceylon are able to obtain in respect of Indian tea gardens is to be found in the Bengal Directory, which gives little more than an alphabetical list of plantations. In this respect, as well as in the matters of roads and transport, Ceylon is decidedly in advance of India. There is another great advantage, in that Ceylon possesses a popular Governor, Sir Arthur Gordon, who is now travelling in the northern districts of the island, seeing for himself in matters of rice cultivation and water-supply.—*Indigo and Tea Planters' Gazette.*

COFFEE SEED.

From a long tour undertaken a short time ago in Wynaad, we were surprised to find thousands of acres of coffee had died out—on enquiring into the cause, some said, it was leaf disease, others *borer*, but neither of these facts were substantiated by the appearance of the trees, their generally small size, their want of vigor, even in the most favorable situations, such as deep ravines, their general puny condition told another tale to the observant eye. Two causes were evidently at work to produce this sad state of things, these were, bad seed and want of manure, for instance, where the soil was rich, and moisture abundant, as in the bottom of ravines, the trees still wanted a robust appearance. Here the cause was indifferent seed, which very probably had been grown on the same soil and climate for years. Now when it is considered not only do tea planters constantly change their seed, getting it from long distances and chincona planters have been giving fabulous prices for the very best varieties procurable, but English farmers never dream of using seed grown by themselves, but get it from those men whose special trade it is to sell *selected* seed, or from a neighbouring county famous for its strain, then why is the coffee planter contented so easily with the first seed to hand?

We have often been surprised to observe the little attention coffee planters pay to the source from which their seeds are procured. To use seed grown year after year on the same land, is simply breeding in and in, and to take seed from an unmanured or exhausted tree is to perpetuate the evil.

We happened to be talking to two very old planters in Coorg and on asking them if they ever made any exchanges in their coffee seed, they replied in the negative, it was not their custom and we believe they were doing simply as others were doing.

One hardly ever sees goods trains of coffee seed ad-

* A grave mistake. We saw one of the finest tea estates in Java pruned close to the ground with the hope of getting rid of this destructive pest.—Ed.

† The Association gets its statistics from the Directory.—Ed.

vertised for sale, hence the inference is, that planters don't require it, if they did the papers would be full advertisements.—*Planter's Supplement to the S. I. Observer.*

[We never heard this question of seed raised until leaf-disease appeared, It is just possible that in-and-in breeding disposed the coffee trees to its attacks; but, looking at its effects, the surprise expressed at there being no advertiseements for seed is curious.—ED.

IMPROVED PLOUGHS FOR CEYLON.

The Director of Public Instruction has made the following report on ploughs manufactured specially for Indian use by Messrs. Howard of Bedford :—

Trial at Handanduwana on 1st Sept. 1884.

1. Handanduwana is a village in the Pitigal Korale, South of the Chilaw District, a few miles only beyond the Negombo District, across the Mahaoya, and intelligent interest was displayed in the new ploughs by a better class of people than is met with further north, some having come from Kochchikada in the Negombo District, where Mutusambha, instead of the common paddy, is not unfrequently grown. Three of the ploughs manufactured by Messrs. Howard of Bedford, which I had asked their Agents Messrs. Davies & Co., Colombo, to send for trial by Mr. Lushington were here; they were those marked A, E, F, in the accompanying sketch. Their trade designations are (A) "Anglo American (single stilt) hillside turnwrest plough," (E) "Improved 'Vitis plough, Indian pattern" and (F) "Howard's light one horse plough."

2. The plough marked A is a light iron plough, (weighing 80 lb. including pole) with a single upright stilt or handle no wheel, and no coulter. It has a wooden pole attached so as to suit it for being drawn by cattle. It is very much the shape of a native plough, except that it has a mould board and share. Messrs. Davies & Co., report that they can sell it at R15 if sufficient orders are received to enable them to get the ploughs out, packed in dozen cases so as to reduce freight charges.

3. The plough marked E is a very similar plough, but it has a wooden stilt or handle instead of an iron one. It weighs 76 lb. Messrs. Davies & Co. can sell it at R18·75 if sufficient ploughs are ordered to enable them to get out dozen cases as above.

4. The plough marked F is quite unsuited for present Ceylon use, and I therefore say nothing about it.

5. The two ploughs A and E were set to work against 4 native ploughs on a dry paddy field. After the long drought which has prevailed the ground was as hard as a turnpike road, but while the native ploughs could make no proper impression, the two iron ploughs, though drawn by ordinary village buffaloes, did extremely good work, turning the soil well over. Plough A turned a furrow of from 6 to 7 inches deep and about 9 inches wide, while plough E turned a furrow of from 8 to 9 inches deep and nearly a foot wide.

6. After the ploughs had worked for some time, I spoke to the natives present, I desired only private persons to enter into discussion with me, as I wished to get at honest native opinion unbiassed by headmen who might say any thing to please the Government Agent. Two natives as spokesmen objected

(1) That their buffaloes were not strong enough to work the ploughs.

(2) That their buffaloes were accustomed to turn to the right, but these ploughs had the mould board on the right side, and so the buffaloes had to turn to the left.

(3) That they did not want any new fangled ploughs—they wanted tanks. I replied that objection (1) was disproved by the fact that their own buffaloes did work the ploughs and work them well; and, taking this and objection (3) together, I said that Mr. Lushington t ld me that he had been informed that a field at Kurunegala cultivated with iron ploughs which I introduced there at the end of last year had given a yield of over 24 fold, although under the old system it had never exceeded 7 and 8 fold.

As regards objection (2) the difficulty is easily met by having the ploughs made with the mould board on the left side.

After I had finished speaking sixteen ploughs were at once ordered, viz., 13 ploughs of the A type by natives, and two others by Mr. Byrde, Assistant Government Agent, Negombo, and one by Mr. Bever, these two gentlemen being present at the trial.

7. *Trial at Madampe, 2nd Sept.* 1884.

This village is 7 miles South of Chilaw.

To this place Mr. Lushington had removed the 3 ploughs above specified and also ploughs B, C, and D.

There was here considerable opposition to the ploughs receiving a fair trial, one of them (the A plough) had been maliciously injured, but I was fortunately able to repair it, by affixing a nut from one of the other ploughs, whilst a leading native who did not attend, wrote stating that he knew the ploughs would be a failure, in short everything was against us, and nothing for us, the ground here was even harder than at Handanduwana, very wild buffaloes were given us, and every time they bolted, the crowds of natives yelled with delight,* but after some perseverance Mr. Lushington got ploughs A and E fairly to work. The othe ploughs would have had no chance in such hard ground and were not tried.

8. In spite of the opposition, however, three ploughs were ordered, and one landowner on being informed that they were only specimen ploughs, and that he could not receive his purchase for some three months, begged to be allowed to borrow one at once for the ensuing maha-harvest. This, I gladly agreed to, he promising to cultivate two contiguous fields, one with the new plough, and one with the native plough, so as to test the crops obtained.

When I spoke to the natives here, the objections raised were the same as at Handanduwana, and my replies were the same; one new objection was, however, made, that the new plough required four men to work it, whereas the native plough required only one boy: I pointed out that this was not true, for we had been working the new plough with only one ploughman and one driver all the morning, and as a matter of fact it is not true that one boy is all that is used for a native plough.

9. *Trial at Chilaw on the 3rd September* 1884.

Very little interest was manifested here in the test, there were hardly over 50 people present, and, though the ploughs worked, there was nothing special to record except the violent opposition of a man who turned out to be a native ploughmaker. One plough was, however, ordered here by a Madampe man who had followed us down. This was encouraging after the opposition already recorded there.

10. In conclusion, in spite of all opposition which was and is to be expected anywhere to a new thing, and especially on the part of a conservative people, like those of this country, both Mr. Lushington and myself were much encouraged by the manner in which even our opponents quieted down and listened more or less assenting when I spoke to them after each exhibition, and still more were we struck by the very practical result of the orders for ploughs, amounting in three days to twenty.

For my own part, I still hold with Mr. Robertson of Saidapet that the Swedish plough which I took to Kurunegala last year is really the best plough, but the natives take much more readily to Messrs. Howard's ploughs of the A and E type, and as it the natives that we wish to influence, and as these A and E ploughs really do very good work, I would advise encouraging their use as much as possible.

Rich and educated native gentlemen may still be advised to use the Swedish plough, but the general run of the people very naturally prefer the Howard's plough above described, partly because they cost rather less, partly because they are more like a native plough, while the Swedish is like an English plough, and more than all because they are so much lighter and can be lifted and carried about, an especial advantage in the Kandyan districts, where the paddy fields are terraced, although perhaps not so important in the lowcountry, where there are long tracts of level ground. It is to be understood that of the Howard ploughs I do not advise any except A and E.

D, the Ryot plough, is absolutely useless, though some of the people inclined to it as being on their own lines, and thus scarcely a novelty, but it does not turn over the soil at all, and is not what is wanted here. It is to be understood that ploughs A and E are equally suited for use on coconut estates and indeed for use on any ground which is level enough to plough.—H. W. GREEN. D. P. I.

*The time has been in Ceylon when the application of the lash would have produced yells of a different kind.—ED.

ON THE ECONOMIC APPLICATIONS OF SEAWEED.

BY EDWARD C. C. STANFORD, F.C.S.

In 1862, twenty-two years ago, I had the honour of reading a paper before the Society of Arts, on this subject, in this room. The Council marked their appreciation of that paper by awarding me a silver medal, and I cannot forget that the honours of that year were shared by another chemist, my friend, Dr. Crace Calvert, once so well known here, but who has since passed away. When, therefore, I was again invited a little while ago to read a second paper, I felt that some apology was due for not returning to report progress before. I am bound to admit that, like some wanderers through space, the period has been long and the orbit eccentric. For the former, I must plead the difficulty of the subject; for the latter I must remind you that any one who follows seaweed must go to the wildest and most inaccessible shores.

It is extremely interesting to me, and I trust it may be made somewhat entertaining to you, to look back on that paper, with the light of over twenty years' experience, and see how far the views then put forward were right, and how far they were wrong, premising that even failures are excellent lessons. "Many things have happened since then," and new and better sources have been discovered of many of the products then brought forward for the first time. As however, it may be advisable to follow the lines of that paper, I shall first briefly allude to the uses of seaweed for food and for manure, and then speak more at length on the important application of these in the manufacture of kelp, and the production of iodine.

SEAWEED AS FOOD.

In this country, little advance has been made in the use of the algæ as food. The algæ generally contain important nitrogenous constituents, and form nutritious articles of diet, but they have not been popular. We all like a "sniff of the briny," but we do not cultivate a taste for the internal consumption of our marine vegetables. We are equally guilty, however, in rejecting the majority of the fungi, so largely consumed as an important article of food on the Continent. The algæ are closely allied to these, but have the advantage of containing, as far as is known, no poisonous species. The algæ also contain a large proportion of salts which, however, are easily removed, if desirable.

Ulva latissima, or green laver, and *Porphyra laciniata*, or pink laver, are occasionally used in soups. *Rhodomenia palmata*, or dulse, is still sold in the streets of Edinburgh and Glasgow. *Alaria esculenta*, or murlins, is also eaten in Ireland; some others are occasionally used, but, as a general food, the algæ are almost unknown. The sweetest species is the *Laminaria saccharina*, which is usually covered, when dry, with an efflorescence of mannite; a large quantity of this plant yielded me 7·47 per cent of mannite. It appears to be a product of fermentation, and does not exist in the fresh plant. This plant is found only on sandy or gravelly shores.

The best known British species of the edible algæ is the *Chondrus crispus*, or Irish moss; this grows far down on the rocks, and is only uncovered at low spring tides. It is obtained mostly from the west coast of Ireland, and after being bleached by exposure to sun and rain, is largely exported to this country and to Germany. It is a gelatinous species, containing a principle known as carrageenin; it yielded me 63·7 per cent of this substance.

The only other gelatinous British species is the *Gelidium corneum*; this is not very common, but it furnishes the import known as Japanese isinglass, of which it contains 50 per cent. This substance, known also as gelose, was first imported into France, from China, in 1856; it has great gelatinising power, much higher than any other material. It is not nitrogenous, and contains carbon 42·8, hydrogen 5·8, oxygen 51·4.

The following table shows the value of these species in making jelly. The melting point of the jelly is also appended.

1,000 parts of water require of—

	Parts.	Proportion.	Melting point.
Gelose	1	1	90° Fahr
Gelidium corneum	8	2	90° „
Irish moss (*Chondrus crispus*)	30	75	80° Fahr.
Isinglass	32	8	70° „
Gelatine	32	8	60° „
Carrageenin	36	9	70° „
Agar-agar (*Euchemia spinosa*)	60	15	90° „

It will be seen that gelose has eight times the gelatinising power of isinglass and gelatine; but the melting point of the jelly is too high to melt quickly in the mouth, hence gelatine is still the favourite.

The carrageenin has evidently become altered by evaporation. Gelose jelly keeps well, the others soon get mouldy Although not fit for jelly, gelose may be valuable in the arts as a substitute for gelatine, which it so much exceeds in gelatinising power. I would specially suggest its use as a substitute for gelatine in the production of instantaneous photographs.

The *Euchemia spinosa*, or agar agar, is an Australian alga, and another important gelatinous species. The algæ form a large article of food consumption in China and Japan; some years ago I procured some of these samples, one was a dark green frond, and the other two were cut up from it, about the size of vermicelli; I append the analyses of three and of a sample of our own laminaria from Loch Eport in North Uist.

EDIBLE SEAWEEDS.—JAPAN.

	I.	II.	III.	IV.
Water	19·20	19·20	21·50	41·00

Silica	9·40	13·50	3·47	5·21
	100·00	100·00	100·00	100·00
ANALYSIS SALTS.				
Potash	31·90	16·20	40·95	28·26
Carbonate soda	14·61	14·41	5·35	5·00
Sulphuric acid	9·58	8·99	12·33	13·34
Chlorine	39·28	27·52	44·74	51·74
Iodine	0·3171	...	...	0·2946

No. I.—"This is a good average sample, worth to-day, in this market, 11 taels, which at 6s. 6d., the average value of the tael is 71s. 6d. per picul of 133 lb.; therefore one ton (16·75 piculs) would cost, in Shanghai, £57 4s. It can be cut finer, and then the price, if it is of the deep green which this is when it leaves me, would be about 14 taels per picul, or £72 10s. per ton."—*Extract from letters.*

The sample is green and evenly cut about as fine as vermicelli.

No. II.—"This is the worst sample I can find, worth 2 taels, which is £11 8s. per ton. The unent leaf would be more valuable than this if of the colour of No. I. It would fetch £16 per ton."—*Extract from same letters.*

This sample looks like the former deteriorated.

No. III.—This was apparently the uncut weed. It much resembles in colour and appearance No. IV.

No. IV.—Laminaria, cut in Loch Eport, North Uist; colour, dark green. Quotations by Mr. Frazer, Yokohama, September 18, 1868:—Fine cut, £17 9s. 8d.; fine brown, £15 10s. 9d.; large green, £9 14s. 2d—per ton. Specimens of No. IV. were sent out to Yokohama, but they did not take the market. It is remarkable that so high a price as 72s. 6d. per cwt. (or nearly 8d. per lb.) should be realised there for this seaweed for dietetic purposes.

The taste for marine vegetables must be acquired, but those who have eaten them often are said to become very fond of them; and I have known some gentlemen in the Highlands, no mean judges of diet, who consider a dish

nf dulse, boiled in milk, the best of all vegetables. There is no doubt that a valuable food is lost in entirely neglecting the algæ; but I shall show, presently, how much of this may be recovered in an available form.

SEAWEED AS MANURE.

This appears to me to be one of the worst applications of seaweed, and I do no. think it has increased; farmers are beginning to find out that it seldom contains less than 80 per cent of water, often more; and that for the actual manurial value in it, it may be very expensive if a long cartage is required. Four tons of water, at least, must be carted for every ton of dry manure, and when dried there is much additional expense, and it is very bulky. The dry weed contains an average of 2 per cent of nitrogen, so that, as it is used, it contains less than ½ per cent. The chemical value is very little, except from the potash contained; but the mechanical value may be greater, as in covering root crops as a protection from frost, or where the soil is simply sand, and it binds it together. However, the cartage of water and the manufacture of soil are expensive amusements, and seaweed is not much used where there is high farming. It appears also, where continually used alone, to impoverish the soil; it is like feeding a dog on butter. The residue of seaweed ash, or kelp waste, one ton of which is equal to forty tons of wet seaweed, and contains all the phosphates, is quite unsaleable for manure in this country. It may be remarked, too, that in the wet climates of the west of Ireland, and of Scotland, where it is mostly used, the application of water is quite a superfluous operation for the farmer.

Another application of seaweed, which I mentioned before, was the manufacture of paper. As far as I know, this has only been carried out in France, on one plant, the *Zostera marina*, or grass wrack, a material largely used in this country for stuffing mattresses, and for packing light furniture. Some curious specimens of this plant, rolled up in little balls of fibre, were shown here at that meeting, as thrown up by the sea at Majorca and Minorca; and soon after it created a good deal of attention, having been proposed as a substitute for cotton; it contains litle fibre, however. It grows in enormous fields, on sand-banks, and is widely distributed, and is to be found in almost every ocean; it is a pure marine plant, with flowers, having nothing in common with the algæ except the habitat. It is often found on the shore perfectly bleached. All the algæ are cellular, and contain no fibre, but properly treated they make a tough transparent paper, to which I shall have to allude presently.

THE MANUFACTURE OF KELP.

This crude substance which, for many years, made the Highland estates so very valuable, was at first made as the principal source of carbonate of soda. At the beginning of this century it realised £20 to £22 per ton, and the Hebrides alone produced 20,000 tons per annum. The importation of barilla then began, and for the twenty-two years ending 1822, the average price was £10 10s. The duty was then taken off barilla, and the price of kelp fell to £8 10s.; and in 1823, on the removal of the salt duty, it fell to £3; and in 1831, to £2. It was used up to 1845 in the soap and glass factories of Glasgow, for the soda. Large chemical works were then existing in the island of Barra, built by General McNeill, for the manufacture of soap from kelp, and a very large sum of money was lost there. Two tall octagonal chimneys were still standing not long ago, but have now succumbed to the gales. In the meantime, soda was being largely made by the Le Blanc process, and superseded kelp, which was always a most expensive source, yielding only about 4 per cent, often less than 1 per cent; it must have cost the soap-makers what would be equal to £100 per ton for soda ash, the present price of which is £6.

The manufacture of iodine and potash salts then began to assume some importance, but the kelp required was not the same; that which contained the most soda containing the least iodine and potash. Chloride of potassium, the principal salt, was at one time worth £25 per ton. The discovery of the Stassfurt mineral speedily reduced this price to about a third, and the further discovery of bromine in this mineral, also reduced the price of that element from 38s. per lb. to 1s. 3d., its present price. The amount of bromine in kelp is small, about a tenth of the iodine, and not now worth extracting. Large quantities are now produced in Germany and America. More recently, the manufacture of iodine from the caliche in Peru has attained large proportions, and has so far reduced the price of that article, as to make its manufacture from kelp unremunerative. In a paper, compiled for the British Association, published in 1877, I estimated the then total production of iodine in Great Britain and France, at 2,000 kegs of 1 cwt. each; and the future production of Peru at 6,000 kegs; an estimate which is now being rapidly realised.

In 1882, amount of iodine exported from Peru was 205,800 kilos., or 4,116 kegs, divided as follows:—

To London	120,900	kilos.
„ Hamburg	62,100	„
„ New York	22,800	„
	205,800	„

The present annual output is estimated at 300,000 kilos., or 6,000 kegs.

On the other hand, the present manufacture of Great Britain and France is less than 1,000 kegs, the production of France being now reduced to almost nothing, and the kelp sold as manure.

I append an abstract of a table in that paper, showing the imports of kelp into Glasgow, to which city or its district the manufacture of British iodine has always been confined.

The prices given are the average prices for the year; higher than the maximum, but not lower than the minimum, have been reached. It is remarkable that we are now coming back to exactly the price of 1841, forty-three years ago, and also exactly to the price of twenty-two years ago, when my first paper was written. Potash salts, however, were then three times the present price.

IMPORTS OF KELP INTO CLYDE.

Five years, 1841 to 1845.

Tons of kelp, 1,887 in 1844 to 6,086 in 1845; average 3,133. Price of iodine per lb., 4s. 8d. in 1842 to 31s. 1d. in 1845; average 11s. 9d.

Ten years, 1846 to 1855.

Tons of kelp, 3,627 in 1846 to 11,421 in 1850; average 3,627. Price of iodine per lb., 8s. 8d. in 1851 to 21s. 3d. in 1846; average 12s. 11d.

Ten years, 1856 to 1865.

Tons of kelp, 6,349 in 1856 to 14,028 in 1863; average 9,730. Price of iodine per lb., 5s. in 1863 to 13s. 8d. in 1856; average 8s. 10s.

Ten years, 1866 to 1875.

Tons of kelp, 8,116 in 1868 to 10,923 in 1874; average 9,187. Price of iodine per lb., 10s. in 1866 to 34s. in 1872; average 15s. 11d.

Seven years, 1876 to 1883.

Tons of kelp, about 6,000 to 8,000; average about 7,000. Price of iodine, 5s. in 1883 to 15s. 6d. in 1879; average about 10s. 2d.

Total average kelp import, 1841 to 1883 (42 years) 6,750 tons. Average price of iodine per lb., 12s.

So that the present price is only about 40 per cent of the average value. The great fluctuation in the price, and the small bulk of the article in proportion to its value, and the limited production, have led to great speculation, and I have no doubt a few kegs might still be found here and there in London which were bought some years ago at a pretty high price, and are still waiting the improbability of a turn in the market.

The amount of iodine in seawater is so minute, that it is extremely difficult to detect by ordinary tests; by evaporating down two portions of seawater filtered and unfiltered, each over 14 gallons, and by employing a delicate colour test, I have succeeded in estimating it. The seawater was collected carefully in the Atlantic, west of the island of Tyree. I found in 1,000,000 grs. measure (14·2857 gallons) of unfiltered seawater, ·003572 or 1 in 280,000,000; in 1,000,000 grs. measure of filtered seawater ·003442 or 1 in 291,000,000. The unfiltered water might be expected to contain more iodine from minute algæ in suspension, although it appeared clear. Kortstoffer, who estimated it in the Mediterranean, puts it at 1 part in 50,000,000. Bromine is easily detected; sea water generally contains about 6 parts in 100,000, and of chlorine

about 2 per cent. Professor Dittmar, who has been working out the seawater samples of the *Challenger* expedition, has discovered a remarkable relation between this element and that of the chlorine which he has kindly communicated to me. He finds the relation in the great number of samples examined (77) to be constant in the proportion of ·340 bromine to 100 chlorine. He finds the average amount of chlorine to be 1·9 per cent, or 19,000 parts in 1,000,000 and of bromine ·00646 per cent, or 64·6 parts in 1,000,000, or 18,422 times as much as my mean result for the iodine. The Woodal Spa has been long known to be very rich in iodine and bromine; a recent analysis by Wright giving of chlorine 11113·73 parts per million, bromine 49·7 parts per million, iodine 5·21 parts per million. Here the relation of bromine to chlorine is ·44 to 100, and the iodine about a tenth of the bromine; in seawater the proportion of iodine is a very minute fraction of this. Examination of the brine and the mother liquor from the salt mines of Cheshire failed to detect iodine. The algæ possess the power of assimilating the iodine to about ten times the extent of the bromine. I append estimates of iodine in a number of algæ, those of the Laminaria and Fuci are the average of a great number of specimens collected at different times of the year, and all round Great Britain and Ireland, the Channel Islands, and the Isle of Man, and including Orkney and Shetland, Iceland, Denmark, and Norway. I append also estimate of the iodine in several of the giant algæ in the Falkland Islands, for which I am indebted to Governor Kerr, and Mr. F. G. Cobb, of the Falkland Islands Company.

These gigantic species are seen in this country for the first time in the fresh state, and little is known about them. The macrocystis is said to grow to a length of 1,500 ft., or over a quarter of a-mile in length. It grows in 10 fathoms water in Stanley harbour.

The *d'Urvillea* forms stems branched like trees 12 ft. or 14 ft. long, and a foot in diameter. All these weeds are thrown up in enormous quantities on the shores of the Falkland Islands, and along the Straits of Magellan, making it difficult for a boat to approach them.

In the foregoing table the Laminariæ and the Fuci are the kelp-producing species.

It is remarkable that the three gelatinous species, *Chondrus*, *Gelideuna*, and *Euchemia* contain little or no iodine.

It is noticeable, too, that the *Enteromorpha*, or sea grass, a plant which retains, when dry, a very storng odour of the sea, contains no iodine.

It is also remarkable that the giant algæ contain so little iodine, growing outside the influence of the Gulf Stream, which, rightly or wrongly, has been supposed to be the iodine carrier. It is a curious fact that there are certain seeds, supposed by the natives to grow on the tangle, and called "tangle nuts." A specimen here from Tyree is evidently the seed of a leguminous American tree, brought over by the Gulf Stream.

It is probable that all animal substances from the sea contain iodine; its presence has been long known in cod-liver oil, a substance supposed to be rich in it, and to owe most of its valuable medicinal property to it, but I found, after investigating a good many various specimens of this oil, that the amount is infinitesimal. The liver itself contains double as much; oysters, especially the Portuguese variety, have also been said to contain a good deal. The following are my results:—

There are two distinct and well-defined varieties of kelp. Cut weed or black-wrack kelp, and drift weed or red-ware kelp. Cut weed kelp is the old soda-producing variety, and is made from the three *Fuci*, *Fucus vesiculosus*, *F. nodosus*, and *F. serratus*; these grow on the rocks in the order named, the latter being the most submerged and containing the most iodine, though all contain but little. The plants are cut at low tide, floated ashore, dried and burnt; the weed does not soften much by rain, and it can always be obtained in the fine natural harbours of the West of Scotland and Ireland. This kelp, burnt into a dense fused slag, contained the most carbonate of soda, and was that variety which employed so many poor crofters and cottars, and enriched so many highland lairds. It is now worthless, and the Fuci, which hang from the rocks at low water in luxurious festoons in these lochs, are now entirely unutilised. I have seen 10,000 tons of this weed cut in a single loch, in a few weeks of summer.

The drift kelp is made from two varieties of red weeds, or Laminaria, the *L. Digitata*, and the *L. Stenophylla*, the former known as tangle; both are always submerged, and are torn up by the violent gales, so common on the west coast; both are sometimes cut in Ireland with long hooks under water from boats These plants, especially the latter, suffer very much from rain, and are often, after drying, almost valueless; but if well saved, contain ten times as much iodine as the Fuci.

This is the only kelp now used for making iodine, and it ought to be burnt into a loose ash; but although they employ a different material we have to deal with the same people, and they still insist on raking it into a molten slag, with iron clauts, at great extra trouble, so much so that the men of the family are obliged to do this part of the work, under the erroneous impression that it will weigh heavier, thus mistaking specific gravity for weight; the fact being that they drive off more than half the iodine, and a great deal of the salts, spending several extra laborious hours in reducing the value to a half. It may be asked why we allow it? An incident which occurred to me may answer that question.

Some years ago, when I had to take a large quantity of black-wrack kelp in North Uist, it was made to enable the people to pay their rents, and could not then be given up, though it has been since. I tried hard to get some improvement made in the direction of burning the weed at a lower temperature. The people were assembled in great numbers, and the sheriff eloquently harangued them in Gaelic for me. Their objections were threefold: it would not yield so much, it would not be so good, and it would take too long. The late Sir John P. Orde, the proprietor, and his factor were present, and it was agreed at last that the most experienced kelper and myself should try the experiment, each to have a certain quantity of weed weighed out to him, and each to burn it his own way. As I expected, my lot was finished first. The yield was 25 per cent greater, and the product was also, weight for weight,

25 per cent more valuable. Any one can understand this double advantage of ash *versus* slag. The old man, my opponent, on the result being explained to him, made a remark in Gaelic, which was translated for me as follows:—"I have been making kelp for fifty years and more, and am I to be taught by a young Sasseuach with no beard on his face to speak of?" That was the only result of the experiment. How could I explain to him, especially in Gaelic, the difference between specific gravity and weight, to say nothing of quality? As they would not improve the process, the work had to be stopped, and their evidence before the Royal Commission shows how much they have missed it. We took away their clauts, but it was no use; landing once in the middle of the night, I came upon a group hard at work with new irons, raking off the salts, and making themselves hideous, for so intense is the heat, that the soda volatised gives a strong monochromatic yellow flame which does not improve the beauty of the workers.

To show that this extraordinary idea still prevails, I quote the following from a daily paper, referring to the island of Tyree this year:—

"The men attending the kilns used to turn over the burning mass with iron 'clauts,' but about two years ago the company forbade the use of the 'clauts,' and the kelp is simply reduced to ashes instead of a hard substance. It may be better fitted for manufacture in this state, but it is also evident that it will take more of it to make a ton than by the old process."

It has one advantage for them, being on the sandy shore, or single, it enables them to rake in, and embody with the fused kelp a quantity of sand and stones. We sometimes get a block of granite thinly veneered with kelp from our Irish friends, to remind us, I presume, of their national wrongs, and take a slight revenge.

The great heat involves the additional disadvantage that the carbon reduces the sulphates to sulphides, which involve considerable expenditure of oil of vitriol to decompose them, so that sulphur thus deposited is one of the bye-products of the lixiviation of kelp. We are therefore compelled to reverse the ordinary process, and manufacture sulphur from sulphuric acid.

The usual yield of kelp from 100 tons of wet seaweed is 5 tons, and as only half of this is soluble, $2\frac{1}{2}$ tons forms the total valuable product of the labour of cutting, carrying, drying, and burning 100 tons of wet seaweed; the burner, in many parts, does not receive more than £2 per ton, sometimes less, so that all this labour is done for 2s. per ton of weed. When it is also remembered that bad weather often reduces this payment to nothing, it is easy to understand that this occupation is soon given up where any other employment can be obtained. Moreover, the weed is dried in a climate where a native comes up to you with the rain pouring off his hat and nose, and outrages your sense of sight by informing you, if he knows "the English," that it is "a wee misty." The large mass of material to be dealt with, the stormy character of the coasts, the constant moisture of the climate, all tend to still further reduce the quantity obtained. Even with favourable conditions, the yield is only 5 per cent which is quite inadequate to afford profit either to the maker or to the lixiviator.

These evils were fully pointed out in my former paper, and a method was then suggested by which several new products could be obtained, and the whole of the iodine secured. I proposed to submit the seaweed to destructive distillation in iron retorts, thus obtaining a loose, porous charcoal, which retains the salts and the iodine; ammonia, acetic acid, and tar were obtained from the distillate. In looking over the tables published in my former papers, some of the diagrams of which are once more on the wall, I notice that the amount of iodine lost in kelp was much under-estimated; much too low a figure having been taken for the produce of iodine. The amount of kelp then made was 10,000 tons in this country, and 24,000 in France; and I estimated the loss of iodine, in this country alone, at 50,000 lb. annually, it really was about three times that amount, or 150,000 lb. worth, even at the present low price, £37,500, a sum in excess of the whole value of the additional new products proposed to be recovered.

The Duke of Argyll was the first to see the value of the improvement suggested, and the new process was first carried out in his island of Tyree, in 1863, where works were erected for the purpose; soon afterwards works were also erected in North Uist, under an arrangement with the late proprietor, Sir John P. Orde; and more recently in Ireland.

In some respects Tyree was the best place that could have been selected, in others, the worst. The wildness of its shores, and its numerous outlying rocks, make it the deposit of much drift weed. The inaccessibility and the great difficulty of landing heavy machinery, &c., made the erection of works extremely difficult. The factor calculated that 30,000 tons were used annually for manure, and that four times that quantity was lost. Our calculations were based on recovering 16,000 tons of this, and if even that quantity could have been obtained, the works there would have had a very great success, and turned out more iodine than all the other Highland shores put together. It is impossible, however, to estimate the amount of seaweed thrown up in a storm, and the sea has an awkward habit of calling again, and removing a good deal of it, or covering it over with sand. This seaweed is also much injured by rain, which soon washes out the salts and iodine. It is a nitrogenous substance, and is quickly devoured by maggots, which become flies, and the material, like some other riches, speedily takes to itself wings and flies away, so that when once I carted a large quantity to the works for experiment, some knowing ones observed that the Sassenach had taken a great deal of trouble to put in the material, but it would not give him any kind of pains to put it out, as it would leave him of its own accord. I may add that it did not; there is nothing so offensive as rotten seaweed, but I had preserved the weed with chloride of calcium. In the winter the long sea rods are thrown up, and these when properly stacked bear a good deal of exposure. There was much difficulty in getting the people to collect these at first, for it was a new thing, and they did not believe in it. They soon found out, however, that it affords winter employment for what they call "a lairge sma' family," and which, to do them credit, most of them possess, as children can work at it. It consists simply in stacking the tangle out of reach of the tide. This work has been going on ever since 1863, and none is lost that can be secured. The works in Tyree and in North Uist are still continued, to the great advantage of the people. For the latter the taugle is also collected in South Uist and shipped to Loch Eport. Both these islands also yielded large quantities of black-wrack kelp, which is now entirely given up.

The works were lighted with the gas obtained by distillation, but after the gas has passed through all the purifiers, it still burns with a strong monochromatic yellow flame. The ammonia obtained is all used as manure for the farm; for whatever other business you follow in these outer islands, you must be a farmer, to feed your horses, &c. The tar is used for the roof of the works; and I may state here, that after great experience of large roofs, many of which have been blown away, I prefer a lattice girder low felt roof. No one who has not witnessed a winter gale in one of the Hebrides can from an idea of it. We find it advisable to raise the walls two feet above the girders on each side. I would also mention here that there is no building so efficient or suitable for the damp climate of these outer islands as concrete. The shingle of the shore is always there as the bulk of the material, and cement only has to be sent out. A vessel loaded with quick lime, anchored off one of these islands in a gale, is not a happy or a safe possession, and I know from experience that it does not contribute to the sweetness of sleep.

Iron retorts, heated by coal or peat, were at first used, but these were superseded by brick ovens, which are now employed without fuel. The tangle swells in the retort, and produces a charcoal of great porosity, from which the salts are easily washed out, and there are no sulphides. The residual charcoal is a very efficient decoloriser and deodoriser, but has never been largely used for these purposes. I shall mention presently an application of it.

The following analysis shows the comparison of this charcoal with that from bone. It does not in any way

approach the composition of that from wood:—

	Seaweed.	Bone.
*Carbon	52·54	11·77
Phosphates	10·92	77·70
Calcium carbonate	15·56	8·43
Calcium sulphate	—	·35
Magnesium carbonate	11·34	—
Alkaline salt	5·70	1·09
Silica, &c.	3·94	·66
	100·00	100·00
*Containiug nitrogen	1·75	1·5
Containing ammonia		

My experience in the use of peat may be worth recording. I found it give a very fair red heat; we cut and stacked about 600 tons a year of good quality in North Uist, it cost 2s. 6d. per ton, and I do not think it can be obtained for less. There was no royalty or rent, and the bog was close to the works. It required three times the quantity compared with coal, which greatly increases cost of firing. There is this peculiarity about peat that, where a large supply is required, its cost increases with the quantity collected, because a larger area must be worked.

The winter tangle forms but a small part of the seaweed used for kelp. In the spring and autumn large quantities of Bardarrig or tangle top come ashore, and this is the substance most difficult to deal with. It is ruined for kelp-making by rain, and it will not repay cartage to a long distance. Even washing about in the sea spoils it. To work it by my process would require a large number of small works, which it out of the question, so that it is still mostly made into kelp in the old way, with all its attendant evils. It is this substance which I propose now mainly to deal with. I am convinced that no process will deal effectually with it unless it will afford the means of removing it to central works, say at Glasgow, involving a cost for carriage equal probably to the cost of the weed, doubling in fact its first cost. There are two ways of removing it, either wet or air dry. I prefer the latter, although I have proved that it can be perfectly well kept in a silo, a specimen so kept for several months having reached me perfectly good, and still containing 83·8 per cent moisture; and it has been also proved that such a covering of earth as that used for potatoes is an available silo. Most of this material can, however, be got air dry, if, as soon as obtained, it is put in a rick and thatched over, a good deal of it being lost at present while they are waitiug for enough to burn into kelp, which cannot be made in a small quantity, and for a way they have of putting it in small stacks to get damp again, because they object to burning it too dry. Twenty thousand tons of this dry material could easily be got in Ireland alone. Four hundred thousand tons of the black wrack was the usual annual collectiou in the Hebrides in former years, now all unutilised, so that there is ample material if use can be fouud for it. It is a well-known fact that the Fuci grow better when regularly cut.

We are not, of course, limited to Ireland and the Highlands, as any demand for the raw material would offer up new and very extensive sources of supply.

The difference between kelp-making and distillation in retorts is shown by the following actual experiment on eight tons of tangle. Four tons were burnt with great care into kelp, and four tons were carbonised in a retort with the following results:—

	Cwt.	Per cent.
Kelp produced	15	18·7
Char ,,	30	37·5
	Salts. cwt.	Iodine. lb.
Produce of char	8·77	29·25
,, kelp	6·57	13·27
Loss in kelp	2·20	15·98
,, per ton of tangle	0·53	4·00

As a rule the kelp does not contain anything like this. The presence of sand particularly adds much to the volatility of the iodine.

A rich sample of seaweed ash, exposed in a platinum capsule over an ordinary Bunsen burner for twenty-four hours, will not retain a trace of iodine.

The sand in kelp is either shell sand, which is mostly carbonate of lime, or flint sand, which is silica; both are highly prejudicial, as the followiog experiment shows—100 grains of a rich seaweed ash was in each case heated for ten hours over an ordinary Bunsen burner.

	Per cent.	lb. ₱ ton.
The ash contained of iodine	·8930	20
The ash after heating ten hours	·4911	11
The ash with 50 per cent limestone	·3572	8
The ash with 50 per cent sand	·2235	5

NEW PROCESS.

The salts made from kelp at present are as follows, taking an average on 20,000 tons:—

	Per ton.
Muriate (95 per cent potassium chloride)	5 cwt.
Sulphate (75 ,, potassium sulphate)	1·8 ,,
Kelp salt (sodium chloride, containing carbonate = 8 per cent alkali	3·8 ,,
	10·6

Iodine, 12½ lb. per ton.

I found, in the first instance, that these salts could be easily extracted from the seaweed, by simple maceration in cold water; the amouut so removed from air dry laminaria is pretty regularly about one-third of the weight, or 33 per cent, of which 20 to 22 per cent are mineral salts, and the balance consists of dextrine, mannite, and extractive matter; leaving two-thirds of the plant, or 66 per cent, for further treatment, apparently unaltered.

This residue contains a peculiar new substance, to which I have given the name of Algin; and the cellulose; the whole plant being thus utilised.

The comparison between the three processes will, therefore, be as follows, on 100 tons of air dry Laminaria:—

KELP PROCESS.

Per cent utilised, 18.

Kelp, 18 tons. { Salts, 9 tons. / Iodine, 270 lb. } Residuals—Kelp waste, 18 tons, valueless.

CHAR PROCESS.

Per cent utilised, 36.

Char, 36 tons. { Salts, 15 tons. / Iodine, 600 lb. } Residuals—Charcoal, 36 tons, tar, and ammonia.

WET PROCESS.

Per cent utilised, 70.

Water extract, 33 tons. { Salts, 20 tons. / Iodine, 600 lb. } Residuals—Algin 20 tons, cellulose 15 tons, dextrine, &c.

Showing that the last process has the first advantage of taking out more salts and iodine from the weed than any other; and these, even at present prices, are sufficient to recoup all the expense of carriage and working. Moreover, in the two prior processes, the residuals are those of the first product, in the last these are from the weed itself.

The water extract is carbonised, and the salts extracted. I append analyses of these; they differ from the kelp in containing no sulphides, and in containing calcium and magnesium salts.

AIR DRY (LAMINARIA STENOPHYLLA).

21 per cent salts.

	Per cent.
Calcium sulphate	1·93
Potassium sulphate	9·72
Potassium chloride	31·97
Sodium chloride	48·67
Sodium iodide	1·79
Sodium hydrate	0·13
Magnesium chloride	5·74
	99·95

RESIDUAL WEED (LAMINARIA STENOPHYLLYA).

2·32 per cent salts.

	Per cent.
Potassium sulphate	35·27
Potassium chloride	6·72
Potassium carbonate	5·00
Sodium carbonate	49·97
Sodium iodide	2·63
	99·59

It will be seen that 90 per cent of all the salts are thus removed, and much of those that remain are products of decomposition. These salts are obtained by the carbonisation of the water extract. This is not necessary, and may not be advisable, the salts can be fished out during evaporation. I append analysis of a 2 cwt. sample so fished :—

Calcium sulphate	1·18
Potassium sulphate	14·20
Potassium chloride	27·81
Sodium chloride	55·11
Sodium iodide	1·69
	99·99

Iodine 32 lb. to per ton.

Also of the mother liquor 54° Twad. evaporated—

Potassium sulphate	16·35
Potassium chloride	17·48
Sodium chloride	54·98
Sodium carbonate	5·13
Sodium iodide	5·27
Water	·70
	99·91

Iodine 100 lb. per ton.

We now come to the treatment of the residual weed. If the long fronds of the *Laminaria Stenophylla* be observed after exposure to rain, a tumid appearance will be noticed, and sacs of fluid are formed from the endosmosis of the water through the membrane, dissolving a peculiar glutinous principle. If the sacs be cut, a neutral glairy colourless fluid escapes. It may often be seen partially evaporated on the frond as a colourless jelly. This substance, which is then insoluble in water, is the remarkable body to which I have given the name of Algin. The natural liquid itself is miscible with water, but coagulated by alcohol and by mineral acids. It contains calcium, magnesium, and sodium, in combination with a new acid which I call alginic acid. When this natural liquid is evaporated to dryness, it becomes insoluble in water, but it is very soluble in alkalies. This new substance is so abundant in the plant that, on maceration for twenty-four hours in sodium carbonate in the cold, the plant is completely disintegrated. The mass thus obtained is a glutinous mass of great viscosity, and difficult to deal with on that account. It consists of the cellulose of the plant mixed with sodium alginate. The cells are so small that they pass through many filters, but by cautiously heating it, the mass can be filtered through a rough linen filter bag, the cellulose being left behind, and after the algin is removed, this is easily pressed.

The solution contains dextrine and other extractive matter, and it is then precipitated by hydrochloric or sulphuric acid; the algenic acid precipitates in light grey albuminuous flocks, and is easily washed and pressed in an ordinary wooden screw press. A filter press, made for me by Messrs. Johnson and Company, answers perfectly well for this operation, but not so well for the preceding. It forms a compact cake, resembling new cheese, and has only to be stored in an ordinary cool drying-room, where it can be kept any length of time. If desired, by adding a little bleach during the precipitation, it can be obtained perfectly white. The algin can be sent out in this state, it is only necessary to dissolve it in sodium carbonate in the cold for use. If, however, it be sent out as sodium alginate, it must be dissolved to saturation in sodium carbonate, the carbonic acid is disengaged, and sodium alginate is formed. If potassium or ammonium carbonate be used, the alginates of potassium or ammonium are formed, which are similar to the soda-salt. The bi-carbonates of these alkalies may also be used; but the caustic alkalies are not such good solvents.

The sodium alginate forms a thick solution at 2 per cent, it cannot be made above 5 per cent, and will not pour at that strength. Its viscosity is extraordinary. It was compared with well-boiled wheat starch, and with gum arabic in an ordinary viscometer tube; the strengths employed were as follows; it was found impossible to make the algin run at all over the strength employed :—

			Seconds.
Gum arabic solution,	25 per cent	took	75=1 in 3
Wheat starch „	1·5 „	„	25=1 in 8
Algin „	1·25 „	„	140=1 in 112

So that the algin has 14 times the viscosity of starch, and 37 times that of gum arabic.

I append analyses of two samples of commercial sodium alginate of average composition :—

	No. 1.		No. 2.	
Water ...	17·13		19·30	
Organic matter	59·97		58·125	
Carbonate Soda	18·32	P.C. ash 22·90	17·78	P.C. ash 22·575
Neutral salts	2·98		2·77	
Insoluble ash	1·60		2·025	
	100·00		100·00	
Dry algin ...	67·58		65·50	
Soda (Na_2O)	10·71		10·40	
Per cent of Na_2O	15·85		15·87	

Showing that, excluding the water, salts, and ash, the composition is uniform.

The solution may be alkaline, or neutral, or acid, according to the degree of saturation; if alkaline, it may be made distinctly acid by the addition of hydrochloric acid, but any excess at once coagulates it; a 2 per cent solution becomes semi-solid on this addition.

The evaporation is effected in a similar manner to that of gelatine, in thin layers on trays or slate shelves, in a drying room with a current of air, or on revolving cylinders heated internally by steam; high temperature must be avoided. The solution keeps well. Thus obtained, the sodium alginate presents the form of thin, almost colourless, sheets, resembling gelatine but very flexible. It has several remarkable properties which distinguish it from all other known substances.

Algin, or sodium alginate in solution is precipitated or coagulated by alcohol, ethylic and methylic, acetone and collodion (but not by ether) by acid hydrochloric, sulphoindigotic nitric, sulphuric sulphurous, phosphoric, citric, tartaric, lactic oxalic and picric; salts of cobalt, copper, platinum, nickel, silver, bismuth, antimony, zinc, cadmium, aluminum, chromium, uranium, barium, calcium, strontium and tin chloride and bichloride; mercury pernitrate and protonitrate; iron sulphate (white) and iron perchloride (brown); lead acetate and basic acetate; lime water and baryta water.

The solution is not precipitated nor coagulated by alkalies and salts of alkalies, including lithium, alkaline silicates, potass bichromate (not coagulated by boiling) and chromate; sodium stannate, succinate, biborate and tungstate; magnesium and manganese salts, starch, glycerine, ether, cane sugar, amylic alcohol, boracic acid, acetic, carbolic, tannic, butyric, benzoic, gallic, pyrogallic, arsenious and succinic acids; potass ferrocyanide, mercury iodide, ferricyanide and permanganate; bromine, iodine and chlorine water; molybdate ammonia, tartar emetic and peroxide hydrogen. It does not precipitate the ordinary alkaloids.

It is distinguished from albumen, which it most resembles, by not coagulating on heating and from gelose by not gelatinising on cooling, by containing nitrogen, and by dissolving in weak alkaline solution, and being insoluble in boiling water.

From gelatine, by giving no reaction with tannin; from starch, by giving no colour with iodine, from dextrine, gum arabic, tragacanth, and pectin, by its insolubility in dilute alcohol and dilute mineral acids.

It is remarkable that it precipitates the salts of the alkaline earths, with the exception of magnesium, and also most of the metals, but it gives no precipitate with mercury bi-chloride nor potassium silicate.

It has a strong rotary power on polarised light; Mr. Tatlock estimated it for me as having a specific rotary power of 86·5° on Laurent's polariscope. This again fixes its position amongst animal bodies, gelatine, and albumen, and not amongst such vegetable products as pectin, which is central.

Alginic acid is insoluble in cold water, very slightly in boiling. It is insoluble in alcohol, ether, and glycerine. The proportion of soda ash used is one-tenth of the weight of the weed, and the cake of alginic acid obtained, is usually about the same weight as the weed. The quantity of dry alginic acid is given below :—

	Laminaria Digitata.	
	Stem.	Frond.
Water	37·04	44·0
Alginic acid	21·00	17·35
Cellulose	28·20	11·00

	Laminaria Stenophylla. Stem.	Froud.	Lamiuaria Bulbosa. Fucus vesiculous.	
Water ...	34·5	40·02	43·28	40·10
Alginic acid...	25·7	24·06	17·95	12·22
Cellulose ...	11·27	15·06	11·15	...

FALKLAND ISLANDS GIANT ALGÆ.

Nos.	1	2	3	4	5
Alginic acid ...	11·21	10·09	5·56	7·44	3·34
Cellulose ...	8·13	7·25	3·50	12·95	9·68

The three gelatinous algæ, already referred to, contain no algin.

The cellulose in the tangle is higher than in any other weed, the outside of the stem being rather fibrous. I append also analyses of the ash of three varieties of cellulose dry, unbleached to show the trace of iodine still retained :—

	Laminaria Digitata.	Laminaria Stenophylla.	Fucus vesiculus.
Yield of char. ...	38·36	36·41	44·62
Soluble	11·08	5·27	11·06
Carbon	12·73	14·27	15·93
Ash	14·55	16·87	17·63
Iodine	·12	·06	·05
On air dry plant about	·012	·006	·005

The new process may be tabulated as follows:—

	Per cent.	
Extracted by water—		
Salts	20	
Sugar, mucilage, &c.	10	
		30
Extracted by sodium carbonate—		
Algin	20	
Dextrine, &c.	10	
		30
Cellulose		10
Moisture		30
		100

Of these, I have accounted for the salt, the algin, and the cellulose, leaving the mucilage, dextrine, and sugar for further investigation.

It is not necessary to extract the salts first with water, it comes to the same thing to act on the seaweed at once with soda ash, and to recover the salts by evaporation of the solution, after the alginic acid has been precipitated. In this case chloride of calcium or of aluminum may be employed, the alginate of calcium or aluminium being precipitated. With either salt the alginate is thrown down instead of rising to the surface of the liquid, and the cakes are more compact and easily pressed. In additon to the cheapness with which it can be procured in almost any quantity, as a bye-product in alkali works, now all thrown away, the calcium chloride has the advantage of throwing down the sulphates in the salts, and decomposing them into chlorides, so that the salts consist of chlorides of potassium and sodium, which are easily separated, and do not require the tedious and expensive processes necessary in the lixiviation of kelp. The same remark applies to aluminum chloride, which can be cheaply obtained by dissolving banxite in hydrochloric acid. Either salt can be decomposed by hydrochloric acid, and the calcium or aluminum chlorides recovered; or the salts can be decomposed by sodium carbonate. The calcium alginate, when dry, is very like bone, as the dry alginic acid is like horn. The aluminum alginate is soluble in caustic soda, forming a neutral solution, and giving, on evaporation, a substance like algin, but harder and making a stiffer finish; it is also soluble in ammonia, the salt becoming an insoluble varnish on evaporation. The alginates of copper (blue), nickel (green), cobalt (red), chromium (green) and zinc, are all soluble in ammonia, and form beautiful coloured insoluble films on evaporation. So also do the alginates of platinum, uranium (yellow), and cadmium. The latter is exceedingly soluble in ammonia. The alginate of chromium is also soluble in cold water, and it is deposited on boiling the solution, becoming then insoluble.

With bichrome, algin acts as gelatine, the mixture becoming insoluble under the influence of light. The silver alginate darkens very rapidly under exposure to light, and suggests applications in photography. Algin forms a singular compound with shellac, both being soluble in ammonia; it is a tough sheet, which can be rendered quite insoluble by passing it through an acid bath.

COMMERCIAL APPLICATION OF ALGIN OR SODIUM ALGINATE.

For Sizing Fabrics.—A soluble gum of considerable elasticity and flexibility is a greater desideratum; so also is a soluble substitute for albumen, which can be easily rendered insoluble and used as a mordant. As a finish, algin has the advantage over starch, that it fills the cloth better, that it is tougher and more elastic, that it is transparent when dry, and that it is not acted upon by acids. It imparts to the goods a thick clothy elastic feeling, without the stiffness imparted by starch. It has the additional advantage which no other gum possesses, of becoming insoluble in the presence of a dilute acid, which decomposes starch or dextrine. No other gum has anything like the viscosity in solution, and therefore none will go as far in making up the solution or cover such a large surface. Lime-water, salts of calcium, barium, and various metallic salts can be employed for rendering the coating insoluble. If greater stiffness be required, the algin can be mixed with gum arabic, starch, dextrine, gelatine, albumen, or glue, in any proportion.

The alginate of alumina in caustic soda is a stiff dressing, and in the crude, unbleached state will be a cheap dressing for dark materials; and in the colourless state for finer fabrics. The ammoniated alginate of alumina can be used to give a glossy surface, which is quite insoluble after drying.

As to its use as a mordant in dyeing, I quote from Mr. John Christie, of J. Orr Ewing & Co., to whom I am indebted for the fine specimens of Turkey red dyeing exhibited, some of which are finished and mordanted with this new substance instead of cow dung:—"There is another application of the alginate of soda that occurred to me might be of some interest, namely, in the fixing of mordants, such as alumina or iron upon cotton fibre. I find, so far as I have gone with the experiments very encouraging results. I believe a very large application will be found for the alginate of soda as a dunging substitute. The mordants, when precipitated, seem to have full dyeing power, the results indicating that this substance is capable of taking the place of cowdung, as used in print and dye-works; also as a dunging substitute it will rank with arseniates, phosphate, and silicate of soda, and a number of other salts, which are now largely used for the precipitation of mordants previous to the dyeing of cotton fabrices and yarns."

AS AN ARTICLE OF FOOD.

Algin contains—carbon, 44·39; hydrogen, 5·47; nitrogen, 3·77: oxygen, 46·37; or about the same amount of nitrogen found in Dutch cheese. It has a slight pleasant marine taste, easily overcome if objected to, and may form a useful addition to the kitchen for thickening soups and puddings. It appears specially adapted to replace gum arabic in the manufacture of jujubes and lozenges. To make it into jelly, requires addition of gelose or gelatine or admixture of lemon juice.

It will be useful for some pharmaceutical purposes, as for emulsion of oils, as an excipient for pills and for fining of spirits.

FOR BOILER INCRUSTATION.

The sodium alginate has a remarkable effect in resolving and preventing the incrustation of boilers. My friend, Mr. Spiller, who introduced the first, and one of the best fluids for this purpose, first suggested this application. He found it to precipitate the lime in a state in which it could be easily blown off. Further experience has fully corroborated his opinion. The solution is pumped in with the feed water in the proportion of 1 lb. to every 1,000 gallons. Where hard waters are a necessity, the saving of fuel is considerable.

FOR COVERING BOILERS.

The seaweed charcoal, in conjunction with algin is used for this purpose, and has been largely applied under the name of "carbon cement." It is nearly all charcoal, 3 per cent of the algin being sufficient to make it cohere. Charcoal is known to be the best solid non-conductor of heat, and in this way its application to steam boilers has been made practicable. It forms a cool, light, and efficient covering.

ALGIC CELLULOSE.

This substance bleaches easily and under pressure becomes very hard, and can be turned and polished with facility. It also makes a good paper, tough and transparent, but with no fibre. Alone, or mixed with algin and linseed oil or shellac, it may be used as a non-conductor of electricity, where a cheap material is required.

Although there is still a small portion of the plant not accounted for, which will, I hope, also soon be worked out, I think enough has been discovered to justify the following conclusions :—

1. The only way to effectually utilise sea-weed is to import it in the raw state.

2. By following the wet process the additional cost is fully made up by the greatly increased amount of iodine and salts obtained from the water solution, leaving two-thirds of the plant for further treatment.

3. That by extracting from this the algin and the cellulose we utilise the whole plant, and obtain two new products of considerable commercial importance.

4. That the process is extremely simple and requires no extravagant plant; nor do operations on the large scale present any serious practical difficulties.

5. That the new substance, algin, has very remarkable properties, which may find many applications not yet known, when it can be put on the market.

6. That the demand for such a substance in fixing and mordanting fabrics alone is enormous.

Our annual export of textile manufactures and yarns is valued at £40,000,000, or more than half the value of our total exports; and a large portion of this requires some dressing material to fit it for the market. We import about £200,000 worth of gum arabic, a good deal of which is used for this purpose; and the war in the Soudan is raising its price and making it scarce.

7. That the supply of raw material is almost unlimited. Seaweed damaged by rain is equally available for the manufacture of algin.

I will only add that I bring forward this process with some confidence, as the result of a quarter of a century's scientific work, and an almost equally long practical experience—an experience gained in a wide and wild school. I am satisfied, whether it may be given to me to carry it out or not to the extent it should be, it will become the process of the near future. It immediately possesses the advantage of obtaining known marketable products of considerable value, and it bids fair to open up a new industry which may become one of large extent, supplying as it will new products for which there is an absolute want. On the other hand, the importance of attaching a marketable value to seaweed can scarcely be overrated. No Royal Commission will give the crofters and cottars on the shores of the Hebrides and the West of Ireland anything like the satisfaction that the offer of £1 per ton for all the seaweed they could gather would. In all these places the sea quest might soon become more important than the land question. Moreover, a shipping trade in the raw material itself, is a great benefit to the outlying islands where it is obtained, it necessitates cartage, it tends to the improvement of roads and harbours, it improves communication by bringing steamers, and necessarily brings the people closer to civilisation, and the great centres of industry. This is especially the case where the expenditure of every thousand pounds on the raw material means the expenditure of about as much on carriage. I have reason to know that the lairds of all these shores would not be entirely dissatisfied with such a result. We should all share in the satisfaction of knowing that one more waste product had been effectually utilised.

DISCUSSION.

Dr. Redwood had listened with great interest to this paper, and all the more so from his early associations with the author, and from a recollection of his previous paper on his improved method for obtaining iodine from seaweed. It was very satisfactory to find that Mr. Stanford had persevered in the subject he then took up, and had succeeded in obtaining from seaweed these new products he had described. It was, perhaps, to be regretted that, owing to other sources of iodine having been discovered, his process for its manufacture from kelp had been to a great extent superseded; but that being so, it was all the more satisfactory to find there was a probability of rendering this industry advantageous from the discovery of another and very valuable product. Mr. Stanford drew his attention to the product some months ago, and he had satisfied himself experimentally of the facility with which algin could be isolated, whilst the author had shown that evening how extensive was the field for its application.

Mr. E. M. Holmes said the thanks of the whole country were due to Mr. Stanford for suggesting what might prove a very extensive industry, and one which might benefit the poorer classes of the population in districts where at present many of them were nearly starving. He had recently, at Swanage, noticed cows and donkeys on the beach eating the seaweed thrown up on the shore, and it occurred to him that seaweed might perhaps be utilised as food for animals. When they considered the immense amount of seaweed sold in China and Japan, it was astonishing that so small a use was made of it as food in this country. Laver (*Porphyra vulgaris*) was used to some extent in Devonshire, and it was by no means disagreeable in taste. Mannite, which was another product mentioned by Mr. Stanford, was principally obtained from Italy; but some algæ contained it in considerable quantity, and he saw no reason why it should not be utilised. With regard to the use of seaweed as manure, he knew it was constantly so employed in the Channel Islands, and we certainly obtained our earliest vegetables from those islands. He thought it was an error to regard the manurial value of seaweed merely from the point of view of the salts which they contained. Gardeners distinguished between what they called live and dead soil, live soil being that in which the decomposition of either animal or vegetable matter was going on, and this process apparently had an influence in causing changes of a chemical nature in the soil which promoted the growth of plants; it could therefore be reasonably supposed that the algæ might be more beneficial in the fresh state than when dried. He understood Mr. Stanford to say that the algæ from deeper water contained more iodine than those which grew nearer the shore, but in the table given, the largest amount was from the *Laminaria stenophylla*, which always grew higher on the shore than the *Laminaria digitata*. Another interesting point was that some of the gigantic algæ contained less iodine than the common Laminarias of our own shores. In the "Flora Antarctica," published by Dr. Hooker some years ago, it was stated that Dr. Stenhouse had analysed these algæ, and had found in them a large quantity of iodine, and in one of them a considerable quantity of mannite; but probably so much was not known at that time about iodine, and no doubt Mr. Stanford's analyses were the more correct. But the interesting questions remained, where the iodine came from, and whether as he believed Mr. Stanford thought, it came from the warm waters of the Gulf of Mexico. He should like to ask Mr. Stanford to what he attributed the strong odour of sea water possessed by the *Enteromorpha*, as he stated that contained no iodine. To show the rapid growth of the Fuci, he might refer to a statement in Dr. Landsborough's little book on marine algæ, that at one place in Scotland, where the rocks had been scraped quite bare, the algæ grew to a length of 6 ft. in six months. The idea of keeping seaweeds in a silo seemed a very excellent one, because under certain circumstances, as in wet weather, it was almost impossible to keep it without losing the salts. With regard to the use of algin for pharmaceutical purposes, it had already been employed for emulsifying cod-liver oil, and was found very superior to other agents, especially as it contained a small quantity of iodine. Some time ago he read that some parts of the coast of Mauritius was covered at certain times with immense quantities of foam, caused by mucilage apparently derived from Laminaria; and it occurred to him that perhaps the algæ might be employed for producing a head on beer in preference to quillaia bark, which he understood was now used for that purpose, and which must be of a somewhat irritating character from containing saponin; whereas the algin would certainly be of a harmless character. It occurred to him from the insolubility of the salts of alginic acid, that it might perhaps be useful for waterproofing purposes. He should also like to ask whether textile fabrics became less combustible from its use. With regard to its

substitution for gum arabic, he might say that it was almost impossible of late years to obtain this gum of good quality. That which they now obtained made a mucilage more like that of white of egg than that from good gum. The bean found with the sea wrack was one which was found in the West Indies, commonly called the asses'-eye bean (*Mucuna urens*).

Mr. Cross said it would be very interesting to see Mr. Stanford's results correlated with the main principles of cellulose chemistry. Perhaps the most interesting feature of the algin was the presence of nitrogen, but he had not said anything about the products of decomposition of the algin, such as would throw light on the point whether the nitrogen was essentially connected with the carbon molecule which presided over the whole. It would be very interesting to have some information on these points. There was certainly some evidence of its having the general properties of an aldehyde, and, in some respects, it reminded one of the body recently described as oxycellulose. Whenever cellulose was oxidised it yielded these peculiarly gelatinising bodies. It was impossible in a few words to even indicate the enormous field which was opened up for investigation by the discovery of this substance, and he hoped it would be thoroughly taken up.

Mr. T. Christy said he had brought with him some *Eucheuma speciosa* from the western shore of Australia; and amongst several seaweeds which he had put into commercial use, none gave such excellent results in dyeing and the preparation of mordants. He had had several requests from France to procure further supplies, but though he held out every inducement to the traders on the west coast of Australia to forward this seaweed, he had not succeeded in getting any more. Mr. Greth, in making some experiments with it, and also on some Japanese seaweed, found that it took up 500 times its weight of water, and as a sizing material there was nothing equal to it. He had also tried it in several preparations for damp walls, and found it most effectual both with plaster, lime, and brick walls. Mr. Greth was still working at this subject in Berlin. The use of the algæ in combination with shellac was of great importance, as it prevented the extreme brittleness which arose from the use of shellac alone. It was largely used for this purpose in France, where they were very particular as to the class of seaweed, and next to that from Australia, the weed from Singapore met with most favour. He had lately, however, received some *E. Spinosa* from Borneo, which was even superior to that from Singapore. There was an immense field for the use of seaweed, if a regular supply could be depended upon of these qualities.

Mr. Lloyd said everyone who had passed a heap of seaweed must have noticed the disagreeable smell which came from it, showing that it was most liable to decomposition, and this was the root of the difficulty of dealing with it as food; besides which, few, if any people, knew how to cook it. In Wales it was largely used fried in oil, and he believed it was also used in London to some extent boiled like greens. He was much surprised to hear that seaweed had been kept in a silo, and retained 80 per cent of moisture, knowing its liability to decompose, and the immense difficulty which farmers had found in keeping grass with only 75 per cent of moisture; it would be interesting to know what changes had taken place, and whether the preservation was due to the formation of some acid, or to the presence of salt in considerable quantities. Looking to the precipitating power of one of the products Mr. Stanford had obtained, it occurred to him that possibly it might be useful in the purification of sewage, at any rate in the initial operation of throwing down the solid matter.

Mr. J. M. Thomson said he understood Mr. Stanford that this new substance might be used in photography, and would produce a harder film than gelatine, but he thought there might be a difficulty in easily softening it with water for the purpose of making an emulsion with salts of silver. One point mentioned in the early part of the paper, viz., the affording occupation to the crofters was of great importance. He could speak from experience of the west coast of Scotland, and if by the aid of the system of telpherage, lately brought forward by Professor Fleeming Jenkin, this industry could be developed, it would be of immense advantage to the inhabitants. If there were more men like Mr. Stanford in that district, in dicating, as he had done, the directions in which the crofters might make their work remunerative, less would be heard of crofters' commissions.

Mr. Stanford, in reply, said that algin had been tried in photography, but there was one disadvantage about it, that the silver coagulum was not such a strong one as any of the others. What he had suggested for photography was gelose; it made a good emulsion, and dry plates had been worked with it. With regard to the preservation in the silo, he could only say that the seaweed had been kept for six months, and it was of a kind very difficult to keep containing, very dry, about 35 per cent of salts, and very liable to rot. It was put into a well-built silo, and after six months was taken up apparently unaltered. He could not say what was the exact change which had taken place, nor did he think this was as yet ascertained in the case of hay or grass. He did not, however, think the salt had anything to do with it; it was a description of seaweed which, if air got to it at all, became full of bacteria, and rotted very quickly. He might also say that it had been noticed years ago that when a large quantity of this substance was kept under pressure, that which was kept underneath kept very well. He understood Mr. Christy to be referring to the *agar agar* as the seaweed from Australia which had given so much satisfaction. He had always drawn the line between these three gelatine-producing species and any other seaweed. Some years ago he investigated all the species he could get hold of, and could not find gelatine in any but the *Gelideum corneum* and the *Chondrus crispus*, and it was somewhat remarkable that neither those or the Australian *agar agar* contained either iodine or algin. With regard to Mr. Cross's remarks, he thought that gentleman had already shown that cellulose was sufficiently difficult to investigate without going into any nitrogenous substances. He had placed algin amongst the albumeous and gelatines, and though he had made a great number of experiments on the decomposition products of it, he had not yet arrived at any satisfactory conclusions such as he could lay before a scientific society. This substance had not been known quite so long as gelatine and albumen, and yet the chemistry of both those substances was in almost as unsatisfactory a state as that of algin. He had not tried whether textile fabrics treated with this material would be less combustible, but probably they would be from its containing soda. As to the colour of the *Enteromorpha compressa*, he had not the slightest idea what it came from, any more than he had what caused the odour of the sea, which again would form an interesting subject for investigation to any young chemist who liked to devote his lifetime to it. As to the important question of the deep-sea algæ, and the *stenophylla* which he had given as containing more iodine than the deep-sea tangle, although it grew higher up, the reason was that the *stenophylla* varied very much in composition; there was no plant he was acquainted with which varied so much in the amount of iodine it contained. In fact, all the seaweeds varied very much according to the time of year, the age of the plant, and other circumstances. The *Laminaria digitata*, both the stem and the frond, almost always contained a definite amount of iodine, and though in this case the *stenophylla* had come out with the largest percentage, it might easily have been the other way. With regard to the use of seaweed as food, it was a remarkable fact that in Japan they were used with a large amount of salts in them—as much as 30 per cent when they were sent into the market. He considered that in isolating the algin, we obtained the whole food value, and the whole of the nitrogen of the plant. He was much obliged to Mr. Holmes for the diagrams and specimens he had lent him, and would draw special attention to a specimen of giant algæ from the Falkland Islands, one of which was supposed to be the longest plant in the world, growing sometimes to the length of 1,500 feet.

The Chairman said this paper was a most interesting one, and there were many points in which it might be very profitably discussed if time allowed. He could but congratulate Mr. Stanford on his perseverance with this subject, for he must have had a great many things to damp his ardour. Some years ago he (the Chairman) had an opportunity of going over the North British Chemical Works, where Mr. Stanford's process of distillation was

going on, and he was much interested in seeing the way it was worked. He feared the discovery of new sources for iodine and bromine which was now about the same price per lb. as it was formerly per oz., must have very much interfered with the success of the undertaking. He concluded by proposing a vote of thanks to Mr. Stanford, which was carried unanimously.—*Journal of the Society of Arts.*

THE TRANSPLANTING OF THE CINCHONA-TREE FROM SOUTH-AMERICA TO JAVA.

(Continued from p. 704, Vol. III.)

Junghuhn concluded hence that the great proportion of quinine in the root-bark of the still young trees, which had to grow a good deal, was to be taken as a sign——a prognostic—of the eventual great quinine-proportion in the stem-bark of the full-grown trees, so that he deemed it rational to class the *Cinchona Pahudiana How.* not only among the good, but even among the best known sorts of cinchona, *whatever the learned worthies in Utrecht might have to say against it.*

In 1862 he declared officially that the condition of the cinchona-culture in Java was eminently favourable.

In Netherland, on the other hand, people were less sanguine, and botanists and cinchonologists of reputation had expressed doubts as to the supposed value of the C. Pahudiana, the more as the culture of it was being continued on an immense scale and engulphed great capitals.

To settle the question a full-grown, specimen of the largest trees of this kind, was sent by order of the Governor-General Baron Solet v. d. Beele L.L.D. to Utrecht, to be there examined by Professor Miquel. This was certainly not a half-measure; for the specimen had a length of 24 feet, so that it had to be sawn into six pieces, and dried and packed up with root, leaves, fruit and all.

The botanical examination brought to light that it was the *Cinchona Carabayensis*, a worthless species, already known to Weddell, and according to him not to be exploited for commerce. Also Dr. J. E. Vander Burg at Rotterdam and the known cinchonologist F. D. Vrijdag Zijnen at the Hague, had pronounced the same judgment on this Javan bark: the species was worth nothing and the culture must be stopped.

Junghuhn, however, continued to dissent from the Netherland scientists; but by a Government Resolution dated 11th September 1862, the further propagation of the *Cinchona Pahudiana How.* was prohibited.

This Government measure was no doubt a hard blow to his feelings; but the conviction that it was taken in the true interest of the cause, could no longer reach Junghuhn. The culture languished, and he himself died 24th April 1864 at Bandong of a liver-complaint.*

As his successor Mr. K. W. Van Gorkom was appointed, with the title of Director of the Government Cinchona Cultures.

Here begins a new period, or the Third Act. In reality it was necessary to recommence from the very beginning. On the several cinchona establishments were at that time:

Cinchona Calisaya	...	...	12,093 trees.
„ Pahudiana	...	...	1,139,248 „
„ various sorts	...	...	283 „

The first thing that the new Director aimed at, immediately on entering upon the inheritance, was to extend as much as possible the culture of the good sorts, and to obtain from Government the permission to let alone the bad sort, namely the C. Pahudiana. By degrees it was supplanted by other sorts, and has now almost entirely disappeared from the gardens.

Also the system consistently persisted in, of planting in the woods under shade-trees, was entirely abandoned. The grounds were cleared of wood as much as possible to render them open, as Hasskarl had done before on the Gedeh. Suggestions of professed nurserymen, such as Tesymann, Binnendijk and M'Ivor were gratefully received, so that sowing and setting were henceforth proceeded with most successfully. A brisk intercourse and interchange was entered upon with the leaders of the British Indian cinchona culture, Markham and M'Ivor. In short the affair looked very promising. A chance occurrence in 1865, added a great impulse, the advantages of which could not be foreseen at the moment. Charles Ledger, an Englishman, who had been travelling in South America for 38 years, to buy up Peruvian bark and Alpacas for the European market and for Australia, after years of unavailing endeavours, at last got possession of a certain quantity of genuine cinchona seed* which his old native servant Mamiel had contrived to obtain at his own peril, and for which L. himself had formerly in vain offered considerable sums of money. This seed, fetched with so much difficulty from Bolivia, and preserved with the tenderest care against cold and moisture, arrived at length in London, and was offered for sale to Hooker the botanist. But he having just then set out for India, it was presented to the Netherland Government, who, on the advice of Professor Miquel bought it for the small sum of 130 guilders, to pay 500 guilders more, if the sort and quality should afterwards prove to be good. Mr. Van Gorkom, as early as 1866, announced from Java that 20,000 plants had been reared from it. The sum promised was now paid down to Ledger in London, with which according to Mr. Moens, he was then very contented. But when in 1874 the extraordinary quality and the uncommon success of the Ledgeriana seed came to light, Ledger complains in a letter to Howard, that he had been but poorly rewarded for his pains and devotion.†

"Surely after the success attending the seed sent by me (1865), the Government of India and the Government of the Netherlands should award me a sum of money commensurate with the importance and value of the service rendered." Not improbably, both his countrymen and the Dutch have remained deaf to these complaints. But let us return to the subject of culture.

The young cinchona plants, which were originally not taken for a special sort, were yet, fortunately, not mixed up with the old Calisaya sorts, and in Tjimirocan 8½ *bouws* had been separately planted with them. In 1872 the Director caused a part of this plantation to be pruned to get more air, and on this occasion reaped the first 261 kilogr. of bark, for which, at the Amsterdam sales, the extraordinary price of *f*4,64 per ½ kilogr. was paid. Mr. J. C. Bernelot Moens, who was attached in 1872 as a chemist to the Government Cinchona-Concerns, had proven by repeated tests that the Ledgeriana bark (henceforth called *Cinchona Ledgeriana*) contained twice as much quinine as the best Peruvian-bark from America, and even trees were afterwards found which, on examination, proved to contain even a greater proportion of this alkaloid.‡

So it speaks of it itself that the inferior sorts of which the crops were regularly brought to market were far behind the Ledgeriana cinchona in value, and would be no longer in demand with the quinine manufacturers. Their culture was consequently not extended further, that of *C. Ledgeriana* on the contrary so considerably, that, towards the end of 1881, the plants in the open ground amounted to above 640,000, and in the nurseries to 619,000. Moens has computed that the above 8½ *bouws* planted in 1866, had cast off in 1876 a net profit of *f*48,000, which sum—if the trees had been all felled with root and branch—would certainly have amounted to 100,000 guilders, fully. This may indeed be called a profitable culture, whose results stand out so brilliantly against this disappointments, experienced from 1855 to 1866. But at that time people concerned themselves more about the rights of priority and other highly scientific speculations and interminable scribbling and verbosity.§ I will only revert to the official reports of Junghuhn. Against this, it is refreshing to read in Howard's book the discourse held at the Botanical Congress in 1867 at Paris, delivered by the man who has most contributed to the transferring of the cinchona-trees from America—by Weddell.

* J. lies buried at Lembang, amidst beautiful Cinchona-trees, but, alas! not planted by his hands. A plain white plastered column, without any inscription, forms his monument, which has been desecrated by triangulation by the insertion of a stone, on which: T. T. No. 456.

‡ Haakman, Tijdschrift voor pharm. 1872, vol. 1.
§ Natuurkundig Tjidschrift v. N. I. en vroeger.

After first arguing that the culture of cinchona, begun in 1861 by the English in India, had progressed so far in 1867 that the first crop could appear at the market in that very year, and giving credit to the talent and energy of the English botanists, as well as to the nurserymen and chemists, he very discreetly steps in for a share in the honour for two other nations, for France and Holland. As a gentleman he apologises for being obliged to mention his own name first, to set forth clearly that his travels to Peru—his monograph on the cinchona, and the live and dried objects, seeds, etc. which he brought home—gave the first impulse to the affair. Then he relates the laudable attempts of the Dutch *who had been seven years in advance of the English*, but had made but very little progress *soit par une raisone, soit par une autre*, and ends with the laconic observation that England, by logical experiments, and profiting by the mistakes of others, came almost at once, without striking a blow, to the solution of the difficult problem.

I repeat—such language destitute of the least appearance of hatred or selfishness—is quite refreshing and grateful.

In 1875 the direction of the Neth. India Culture—in consequence of the appointment of Mr. Van Gorkom as Inspector in Chief of the Cultures—was committed to Mr. J. C. Bernelot Moens, who remained at the same time charged with the chemical operations, and to whom was adjoined Mr. Van Romunde, *Controleur* at the home Government of the culture-concerns.

If these had progressed with gigantic strides during the decennium of Mr. v. G.'s management, so that at his resignation two millions of plants of the best cinchona sorts stood in the open ground, and above 200,000 in the nurseries, the produce, the crop of bark for the Dutch market, was not less considerable, and had amounted in 1874 to above 58,000 kilogr. At the same time the scientific import was not lost sight of. A conscientious study of the species—the development of the bark, the chemical virtue, the propagation, the fructification—had been continued with the greatest zeal, and special mention must be made of the innumerable and scrupulous analyses of Moens, and of his botanical-anatomical study in conjunction with the late Dr. Scheffer, in his time Director of the National Botanical Gardens at Buitenzorg.

It was now positively and clearly ascertained that propagation by seed is not attended with deterioration, as was at first feared; that the grafting of good sorts upon inferior stocks was decidedly favourable, and has this advantage that the quantity of the alkaloids alone is modified.

The old idea that for the collection of the bark it was necessary to sacrifice or fell the whole tree, when grown to maturity, had long made way for a better view. In English India, Broughton had begun in 1866 to pollard the trees, in order to be able to lop the new shoots after 4 à 5 years (Coppicing-system) as is done in Europe with oak and ash coppice. But, besides the trees receiving a serious shock by this treatment, from which they do not so speedily recover, the bark thus obtained is not near so good as the stem-bark.

It was therefore an ingenious idea of Mr. McIvor in the Neilgherries, to cover the stems with moss, in order to improve the quality of the bark. He was led to this by observing that the best—the so-called crown-cinchona—always occurs covered with moss. He made experimets in this direction and the result was that, not only was the quality of the bark improved, but that in this way it was possible to strip the stem of a part of the bark and to heal the wound thus made by covering it with moss, in other words, to renew the bark by artificial means. (Mossing and renewing bark.)

By experiments on a large scale the new discovery was crowned with the best success.

The "mossing system" is almost universally practised in Java since 1879, and numerous chemical analyses have shown that the proportion of quinine in the renewed bark increases, and is even trebled. The "coppycing system" is now only practised when a rapid production of bark is required, or when the sort does not allow of the "mossing system"; the felling, or rather uprooting, of the tree, is still practised exceptionally, when it withers, or when the plantation requires thinning.

Lastly, by way of trial, another method has been followed for a short time, viz., scraping off the outer bark; but though this product offered a precious and valuble material for the quinine manufacturer, the "scraping system" has not been continued on account of culture and commercial considerations. If I do not mistake, the Ledgeriana (in chips) realized at the sales in Amsterdam in '79 the enormous price of *f*10·44 per ½ kilogr. The quinine proportion was 13 per cent.

The "coppycing system" in a modified form, by leaving one shoot on the stem, is now generally and successfully practised in Java with the *C. Ledgeriana*.

The harvest of cinchona-bark deserve a moment's further attention, as so little is known about it. Do not expect a description like "Les Vendanges" in Province or Languedoc, or a mill-feast in a sugar-works in East Java, or of the padi-cutting in Java described by Multatuli. The reaping of the cinchona-bark is unattended by poetical accessories, and the work-people are all quiet. In those elevated regions, sparsely populated, and then only temporarily, no clamour whatever prevails. All nature bears an appearance of monotony and gloominess. In the gardens and woods the sun can hardly penetrate, the trees mostly dripping with rain, or from the clouds floating above, and breaking down in a dreadful thunderstorm. Then the labourers—among whom not unfrequently mothers with infants at the breast—experience all the miseries of a mountain-climate at an elevation of 7,000 feet. Shivering with cold, the women sit, sheltered as much as possible by a screen of plaited dried leaves, peeling the lopped branches, and cutting the wet bark to measure; the small silvers, or so-called refuse, is carefully collected in baskets.

The heavier work is performed by men; they lop the branches, or, if the mossing system is followed, they make incisions lengthwise in the stem, at intervals of 3—5 or more centimetres, according to the thickness of the tree, and then strip the stem from below upwards to where the branches begin, but in such a manner, that strips of bark of equal breadth are left alternately on the stem, by which it assumes somewhat the appearance of a fluted column. The strips of bark are then cut into lengths of + 50 centimetres, and the stem, which is partially denuded lengthwise, is entirely enveloped, as is done in Europe to some trees that could not bear exposure to our winters. McIvor at Madras did this first with moss, and hence the name "mossing"; but as this material was soon exhausted in Java, recourse was had to alang-alang, indjoek or dried grass, which occurs in great abundance.

In the course of one year this envelop is removed, then the healing—the granulation we should say—the renewing of the bark is begun, and now comes the turn of the strips left on the tree the preceding year to be stripped off. Then the stem is again bandaged.

The wet bark, after being cut to measure, is dried either in the sun, or artificially, by which the pieces roll up in their breadth and thus form the familiar pipes. The packing is generally in Jute-bags. They weigh about 75 kilogr.

From chemical investigation it is proved that drying in the sun, or by artificial heat, is the same for the bark, and has no influence on the proportion of quinine.

The Government Gardens, situated in the Preanger Regencies, bear the following names:—*Tjiniroean, Rioengoenoeng, Tjiberem, Lembang, Nagrak, Tjibitoeng, Kendang patoeha*, which names are mostly derived from the neighbouring desa or mountain-top.

The private plantations, which already occupy a considerable area, are besides those in Bandong, situated in Krawang and Buitenzorg, and belong to the following gentlemen:—Holle, de Sturler, Dennyson, Meyboom, Holland, and some others.

Also with regard to the *sorts*, of which the culture has been tried since 1852 in Java, and which are now regularly reaped, I will add a few words. Cinchona Calisaya Jav. C. officinalis and C. lancifolia are the oldest; Cinchona Hasskarliana alone remains of H's mission; Cinchona Succirubra we have received from the English from Madras; of the Cinchoua Calisaya Schuhkraft the seeds were procured us by our Consul at La Paz, and the origin of Cinchona Calisaya Ledgeriana has already been explained.

Their collective produce amounted in 1881 to more than 81,000 kilogr. But many of the sorts mentioned are no

longer cultivated, because there are some among them unfit for the preparing of quinine and hence are of little value. In the nurseries only seedlings or slips of C. Ledgeriana—C. officinalis—and Succirubra are now found, the first of which furnishes a superior bark for quinine, with 2 á 8 p. Ct. of quinine. The second (C. officinalis) less rich, but advantageous enough for the manufacture, has an advantage in culture, that it very well endures a severer climate in the higher elevations of 7,000 feet, while the third sort (C. Succirubra) thrives quickly and vigorously also in the lower regions of 3,500 feet, and yields the favourite bark of the apothecary—the red bark.

Of the formerly so highly-lauded Cinchona Pahudiana How. represented by more than a million of plants, nothing more remains than a few specimens, living witnesses for History. As the substantial sort in the row of Botanical Science it has long since disappeared.—*Indian Mercury.*

THE USE OF OYSTER SHELLS IN THE MANUFACTURE OF SOAP.—A correspondent states the fact that in France oyster-shells are reduced to a coarse powder by grinding and stamping. When dried, this powder is sold to the makers of carbonated water. The bitter portion of the shells is during the process separated, and after being carefully collected it is used in the manufacture of soap.—*Independent Journal.*

ORANGE CULTURE.—Orange trees never thrive well, or attain a great age, unless their roots are able to penetrate the subsoil to a great depth. The worst subsoils are sour clay and impenetrable rock. If the subsoil is gravel or loose shaly rock in which the roots can make way, the plants will succeed, and grow in proportion to the quality of the surface soil or the way in which the surface roots are fed. The trees are likely to last longer if the seeds are sown where they have to remain, and they grow more robust.—*Leader.*

CEMENT FOR PROTECTING WOUNDS OF TREES.—It is decidedly advisable to cover wounds on fruit trees made by cutting off branches. You may use any of the following recipes:—Take 1 quart of tar and boil it slowly three or four hours. Add to the boiling tar 4 oz. of tallow and 1 lb. of beeswax and stir till well mixed; then remove the vessel from the fire and stir till the contents begin to thicken. Have ready 1 lb. of dry and sifted clay, and stir it throughly until you can stir it no longer. In warm weather this cement is soft enough to be easily spread with the point of a knife. When applied to wounds on trees it completely excludes moisture, does not harden or crack, or scale off, yields to the new growth and can at any time in moderately warm weather be pressed by the finger into corners and crevices of the wound which may be uncovered. One of our correspondents says that he has found a cheap and safe application to be that of tar and pounded brick applied with a swab. His experience has been that it will last for years, or until the stub is healed over. An application of gum-shellac dissolved in alcohol, common grafting wax or either of the above preparations is exceedingly useful in preventing season crack where the limbs have been cut off.—*Leader.*

THE water which alights as rain is not the same as the water which existed in the cloud. *That* we must imagine to have been pure water, as it was when present as an invisible gas in the midst of the clear blue air. *This* has already picked up many foreign ingredients also present in the air, through which the falling shower has passed. Like the mineral cloud in the midst of the glacier river, it has carried down with it all it could—more, indeed, than is possible for a cloud of mere triturated rock, like that which the Rhone brings down to the Lake of Geneva; for the rain drops possess not only the power of surface attraction, which is all that particles of rock exert—they are also solvents, and will take into solution all that is soluble in the air through which they pass. The air contains many soluble substances besides itself. All life, and still more death and decay, is always filling it with foreign substances which are soluble in water. Carbonic acid, the product both of respiration and of putrefaction, is largely present in it. Ammonia is present in it. Nitric acid is present in it. Even the chlorine of common salt, thanks to our nearness to the sea, is present in it. The rain dissolves, absorbs and carries down all these things.—*Agricultural Gazette.*

MAKING GAS FROM CITY REFUSE has been tried successfully in New York. A pound of rubbish was picked up at random in the street old rags, leather, vegetable stumps, bones crusts, egg-shells and cigar-ends—and when placed in a retort produced a clear steady flame quite as good as that generally used for illuminating purposes. This quantity gave light for half-an-hour, and yielded twenty-two feet of gas. —*Graphic.*

DISEASE IN BRAZIL COFFEE.—Our papers from Brazil have not as yet confirmed the statement, set afloat by Dutchmen we believe, that the deadly *Hemileia vastatrix* had reached Brazil. But, from the following paragraph in the *Rio News* of July 24th, we gather that the coffee in San Paulo (Santos) had been very seriously affected:—

A S. Paulo paper, the *Rio Branco*, says that the coffee pest is caused by an insect called *Elachista coffeila* and not by *Sequilha*, nor *Saltao*. We wonder which is worse for the coffee!

A STIMULANT FOR TOMATOES.—"Beginner," Wakefield, Mass., asks:—"What artificial fertilizer can be used upon a crop of tomatoes to give a quick and temporary result?" The soil for tomatoes may be easily made too rich, and the vines stimulated to rampant growing rather than to fruit bearing. A light, sandy soil, with a little well decomposed stable manure in the hill at planting, gives better crops than a strong soil heavily manured. Of the artificial fertilizers, a good superphosphate is likely to give the best resuls. A tablespoonful or so to each plant to be worked into the soil at the time of setting out, or rather more applied later, when hoeing, will probably be of good service. —*American Agriculturist.*

CHINA TEA IN BOND IN LONDON AT 6¾D. PER LB.—A correspondent, "R. W. J.," writes to us:—"With reference to your doubt expressed in your review of Mr. Colquhoun's letter to the London *Times* that 'China tea is sold in London as low as 1s per lb.' I send you herewith samples of 100 half-chests bought by a friend of mine, a contractor, who gave it to me at 6¾d a lb. in bond in May last. Having been kept in paper so long, it is musty, but you can judge of the leaf by infusion." The tea, but for its mustiness, is what a Scotchman would characterize as "No that bad." But, however well the buying price might suit a contractor, either the grower or the middleman must have lost by the selling price. But even this tea could not be retailed, after the payment of 6d per lb. duty, at anything less than 1s 6d per lb.

A CORRESPONDENT has sent us a specimen of a twin tea leaf taken off a heavily pruned bush of a very fair hybrid. It is a peculiarity of growth and cohesion which is not very rare, and is referred to in Dr. Master's work on Vegetable Tetratology, in which he says that the union of the margins of two or more different organs is of common occurrence, the leaves being frequently subjected to this change. Occasionally, the leaflets of a compound leaf have been observed united by their margins, as in the strawberry, the white trefoil, and others. Sometimes the union takes place by means of the stalks only; in other cases the whole extent of the leaf becomes joined to its neighbour, the leaves thus becoming completely united by their edges. Although usually the lower portions of the leaf are united together, leaving the upper parts more or less detached, there are some instances in which the margins of the leaf at their upper portions have been noticed to be coherent, while their lower portions, with their stalks, were completely free.—*Indian Tea Gazette.* [Of these curious united leaves, we have seen many in Ceylon.—ED.]

REPORT ON THE METEOROLOGY OF INDIA FOR 1882.

We have received from the Government of India a portly volume, the eighth which has been issued since Mr. Blanford commenced publishing the results of his own observations and of the information supplied to him. Besides other illustrations, there is a map of India showing the sites of observatories and rain gauge stations. As our readers are aware 1882 was a year of excessive rainfall over a considerable portion of Ceylon, so that it may be interesting to compare the figures for a few stations on the continent and in our island. But, first, we may say that Mr. Blanford, referring to a table which gives the number of days on which the rainfall has been measured at 457 states, states that

Table XIV (appendix) gives the number of days on which the rainfall has been measured at 457 stations From this table it appears that the wettest station was Galle, where rain fell on not less than 234 days, and next thereto Port Blair, with rain on 206 days, and Nuwara Eliya with 201 rainy days. The driest stations were, as in the previous year, Jacobabad, where, rain amounting to a total of 2·17 inches fell on 11 days. Shikarpur had the same number of rainy days, but the total fall was 4·91 inches, or more than double the above. The rainfall of Cherrapunji was only 391 inches, and next in order came Mahableshwar with 374½ inches, a very unusual amount, even at this exposed station.

The "only" against Cherrapunji indicates that this, the rainiest station on the face of the globe, came much short of its average of 486·11 inches. The average rainfall of Mahbleshwar has already been mentioned as 257·12, and we notice that Bavda also in the Bombay Presidency, is down for 254·59 and Matheran 245·51. Bombay itself (Byculla Hospital) averages 81·10, while, as a contrast to Mahbleshwar, Jacobabad has only (as Mr. Blanford has pointed out) an average of 4·21 inches. No wonder, if the dwellers in such a climate should be rather dry, as those at Cherrapunji must be somewhat limp. The average rainfall at Madras is 48·72, somewhat over the average of Jaffna, but Mangalore on the west coast of the same Presidency shows 133 39 inches. The average rainfall of Calcutta is 65 64; of Darjiling 121·14, and of Mongpoo, where the Sikkim Cinchona Gardens are situated, 129·46. Cherrapunji is included in Assam, but in the tea districts the average rainfall varies from 156·39 against Sylhet, 117·20 Silchar, 113·99 Dibuaghar, to 94·91 Sibsagar, 95·56 Goalpara, 69·58 Gauhati, 80 24 Nowgong, and 87·29 Shillong. The highest average of twelve Ceylon stations included is for Ratnapura 149 76; the lowest against Mannar 35·32. Nuwara Eliya stands higher than we thought with an average of 101·76. British Burma shows an average of 211·48 at Sandoway, 100·57 Rangoon and only 52·97 at Prome. Of the Ceylon stations, Jaffna had 24·78 inches in 1882, above its average, Mannar 12·57, and Trincomalee 12·00. Kandy had 25·48 excess, and Nuwara Eliya 27·54. No wonder, though there is a reaction this year. Colombo had 6·90 below its average, but it more than made up for this in 1883. Anuradhapura had 10·52 above its average, but Hambantota 5·15 below.

Mr. Blanford states :—"In Ceylon the rainfall was excessive on the hills and at Ratnanapura, and Trincomalee and Jaffna had more than an average fall, and nowhere was there any considerable deficiency." Coming to the figures for 1882 we get for Aden only 1·78, Peshawur 11·45, Delhi 24·89, Simla 58, Naini Tal 104·40, Benares 40·18, Calcutta 61·62, Darjiling 144·18, Buxa 252·93 (of which 82·73 in August !), Silchar in Assam 109·40, Sylhet 176 75 (great and destructive floods), Sibsagar 82·19, Gauhati 66·75 Tezpur 76·16, Bombay 69·23, Matheran 265·70 Mahableshwar 374·49, Jacobabad 2·17, Madura 30·22, Manantoddy 175·61, Madras 50·20, Colombo 79·63, Jaffna 69·22, Ratnapura 149·53, Kandy 111·12 : Nuwara Eliya 129 30 and Hambantota only 31·98.

Mr. Blanford notices that, although 1882 was a year of the maximum of sun spots, its meteorological phenomena gave but slight support to the theory of the effects of sun spots on the weather, and he adds :—

A far more promising field of enquiry, in my opinion, lies in the attempts which have been made, in this and previous reports, to correlate the variations of the several meteorological elements *inter se*, and to trace out their mutual inter-action, under the guidance of the verified laws of atmospheric physics.

In Europe and America, the attention of the leading meteorological physicists would seem to have been concentrated, of late years, mainly on the physics of the vortical movements of the atmosphere, of cyclones, and anti-cyclones, the importance of which is keenly felt, owing to the prominence given to storm-warnings and forecasts of impending weather, among the objects of the national systems of weather report.

In India, storm-warnings also have an importance; but it is chiefly local and restricted to certain seasons of the year; and other and more comprehensive problems force themselves on our attention and await their solution at our hands. Foremost among these are all questions bearing on the vicissitudes of the rainfall. The provinces of India, most subject to drought, are those which present wide expanses of treeless plains or slightly undulating plateaux, furnishing but little vapour to the atmosphere from any permanent source of local evaporation; and which, at opposite seasons, are swept by dry land winds, and alternatively, by the vapour-bringing monsoon. Seasons of drought are due to the unusual and unseasonable persistence of the former winds, and the exclusion of those from the sea; and thus one of the most important subjects, that can engage the attention of the Indian meteorologist, is the physical history of the land winds and the conditions which give them birth. It cannot be pretended that, as yet, we have gained more than some glimpses into the solution of the comprehensive problem, here presented to us. It was observed at an early stage of the systematic study of Indian meteorology, that the prevalence of one or the other of the great wind currents which dispute the mastery of the region in question, is associated with certain features in the distribution of atmospheric pressure; which features are remarkably persistent, lasting sometimes, without any essential alteration of type, through two or more consecutive seasons. But the circumstances which influence the atmospheric pressure, even apart from such as are merely local and ephemeral, are very complex. It has been found that, contrary to European experience, the pressure of the atmosphere is, as a rule, unduly high, when the temperature is also high; and since it is obvious that a high temperature must reduce the density of the atmosphere, and therefore its pressure as a gravitating mass, the conclusion was forced upon us that, under such circumstances, the observed excess of pressure must be due to the condition of the more elevated atmospheric strata; and that the effect of these must be partially neutralized by the condition of those lower strata, the temperature of which alone is recorded in our registers. The evidence afforded by the barometric observations of the Indian hill stations gives strong confirmation to this view.

The discovery thus made of the influence on Indian weather of the far up strata of the atmosphere, we need scarcely point out the connection with this fact of Mr. Blanford's recently developed theory that in proportion as snow falls heavily on the higher ranges of the Himalayas, so is there likely to be a deficiency of rainfall on the plains of India. Mr. Blandford goes on to state :—

But further, we learn from general mechanics that, while variations in the distribution of pressure over continents and seas primarily determine the directions of the winds, the very movement of the air re-acts on the pressure, exercised not only by these winds themselves, but also by the air of neighbouring regions; and we are thus called upon to determine, which of those barometric features, found to be associated with certain prevalent

winds, are to be regarded as primary and productive of the movement of the air, and which, on the other hand, are secondary, and represent rather a loss of the energy of the movement. It seems probable, for instance, that the shoulder of high pressure, which exists over Rajputana during the prevalence of west and north-west winds, is in a great measure a secondary effect of this kind; and similarly, the low pressure which under similar conditions, lies along the foot of the Himalaya. The exceptionally low pressure in the central calm of a cyclone is now generally recognized as an effect of the centrifugal movement of the winds around.

The experience of recent years indicates that a season in which the pressure of the higher atmospheric strata is excessive, is one in which the land winds are unduly prevalent; and by a process of exhaustive reasoning, supported by occasional observation, I have been led to infer that, except at certain times in the cold season, the higher strata of the atmosphere lying over the mountain zone around North-Western and Western India, are the principal and immediate source of these winds.

It would be out of place to enter here on an exposition of the reasons which have led me to this view; and it is my intention to give them in another place. Moreover systematic observation of a kind which we can hardly expect from the class of men who furnish the registers of our observatories, is yet required to confirm its accuracy. What is more especially required now is a knowledge of the prevailing movements of the higher atmospheric strata, as indicated by those of the clouds characteristic of great elevations; and this requires watchfulness and judgment, only to be expected of educated observers, who take an intelligent interest in the conduct of the observations. Such persons are at present extremely rare in India.

It will thus be seen that the laws which govern the movements of the lower atmosphere in which we live, including cyclones, a series of which constitute what, borrowing an eastern term, we call monsoons, are much more complex and distant from human ken than we imagined, and that we must wait for the "more light" which the researches of men like Blanford, Elliott and other observers will throw on the phenomena of air: calm and in motion, dry or saturated with moisture, blowing as a steady gentle breeze, or raging as a destructive tornado over limited spaces or wide areas of our globe. There are many difficulties in the way, but we cannot doubt that the result of all the careful observations now made, recorded, compared and compelled to reveal the laws of the atmosphere will be to enable men to predict and guard against not only storms but seasons of deficient rainfall, such as for centuries back as they recurred spread desolating famines and pestilences over India.

Ceylon is doing its part in this great and useful work, the twelve stations in our island scattered from south to north, from east to west, and reaching from sea level to 6,240 feet, included in Mr. Blanford's list of nearly 500 stations altogether, giving valuable and trustworthy results. Corrections have now, however, to be made in the case of Kandy and Nuwara Eliya from the date of shifting of the barometers up to 1881. The instrument at Galle, it seems, was shifted from 40 to 48 feet above sea-level in June of this year; that at Kandy from an elevation of 1,650 feet to 1,696 in June 1881, while at Nuwara Eliya, so long ago as February 1879, the observing station was removed from 6,150 feet above sea level to 6 240. The elevations, longitudes and latitudes of eight stations in Ceylon, carefully ascertained, are thus given:—

Stations.	Altitudes.	Latitude N.	Longitude E.
Colombo ...	40	6° 56′	79° 52′
Jaffna ...	9	9° 40′	79° 56′
Trincomalee ...	175	8° 33′	81° 15′
Batticaloa ...	26	7° 43′	81° 44′
Hambantota ...	40	6° 7′	81° 7′
Galle ...	48	6° 1′	80° 14′
Kandy ...	1,696	7° 18′	80° 40′
Nuwara Eliya...	6,240	6° 59′	80° 47′

CEYLON PLANTING NEWS.

12th September 1884.

In tea planting the question of germinated seed *vs.* plants is worth considering. The objects to be obtained are of course to have as few vacancies as possible, and that the progress of the plants afterwards may be that of vigorous-growing shrubs.

The season which we are now passing through has, from its abnormal dryness, been a good test of what germinated seed planted at stake can do, as well as of the hardiness of the nursery plants. The drying wind and scanty rainfall—in some districts at least—has been of such an extreme nature during the last few months as to entitle one to regard it as exceptional. We may soon again have another year like this; but the chances are we won't.

Now, like many others, I put out some weeks ago in old coffee a considerable number of fine tea plants, and as I had more holes than plants I finished up the work by means of germinated seed planted at stake.

The plants for some considerable time did well, fought against the adverse season so pluckily, that, if anything like rain had come within six weeks of the time they were put into the ground, the failures would have been very few. But day after day the clouds passed over us, and the much-needed and anxiously-looked-for downpour was nowhere.

The portions facing the south-west did get, from time to time, a slight damping from a flying shower; but the amount that fell was hardly more than measurable, while the parts of the field with a north-east exposure benefited very much less in that way. The germinated seed was all put in in the north-east side.

I have carefully examined the results, and find that in the south-west exposure the failures in the plants are from 7 to 10 per cent, whereas in the north-east they are in some parts as high as 50 per cent. The germinated seeds, on the other hand, are doing well—coming up regularly—and where they had not appeared I found in every instance which I examined—and I examined a considerable number—that they were all on the way. The chances were rather against the germinated seed, for I only put one seed into each hole, and it was all planted in a north-east exposure.

Mentioning my experience to another planter, he told me that germinated seed which he put in this time last year is now as high as from three to three-and-a-half feet, whereas the plants planted out at the same time have not made anything like such progress.

Of course, in regard to seed planted at stake, it is more difficult to protect it from enemies, weeders, rats and such like, than if put out in a nursery. There are cases which I know of where a promising lot of tender tea growing in the open has been levelled in a night by rats, and even the very seed dug up and eaten. Still, all this considered, I am not sure if it be not the better way, when tea seed is cheap,* to take the risk of planting at stake and thus save the trouble and expense of nurseries. Best of all might be to utilize both systems: germinated seed first, with a moderately-sized nursery as a reserve to fall back on in the event of failures

While on tea, I may mention that a certain crack estate near Gampola is said to have 900 lb. per acre of made tea already in this year. Whether or not, however, at the cost of next year's crop by delayed pruning, remains yet to be seen. But all the same it is a wonderful yield, and shows that in Ceylon tea has found its true home. [This corroborates what our Liudula correspondent heard of an anticipated total of 1,200 lb. per acre. If realized over the whole bearing acreage, the yield will, we believe, be entirely unprecedented.—ED.]

* As it certainly is, now.—ED.

From Nawalapitiya comes the report of another tea garden, which has harvested 700 lb. per acre, and the pruning well advanced. Altogether, when one hears of these splendid results, the question uppermost in the mind is: why is this industry only now in its infancy? [When a Dimbula patriarch said to us, "How blind we have all been!" we felt we could scarcely be included; for, the moment we were in a position to cultivate, we tried tea on a pretty good scale.—Ed.]

There is a new rubber-tapper now in the field, which is said to be highly successful. It has solved the difficulty of collecting the sap free from all impurities, is simple and easily worked. Samples of the rubber it has collected have gone home for valuation and report. By and by, the public will have the benefit of the new tool, if it turns out the success which its designer confidently anticipates. From all I can learn, it is yet likely to render rubber culture remunerative if it be grown in large areas.

Bug and black fungus are, I think, at present a more serious evil than leaf-disease. It is simply awful. I was hearing of an estate with a considerable extent of Liberian coffee—perhaps 100 acres or so—the manager of which has received instructions to cut the Liberian all down, owing to the terrible hold these plagues have upon it. Let us hope the heavy rains of the north-east monsoon will do something towards their removal, for the grip they have is a very strong one, and in some of the affected patches, whose area increases, alas! rather than diminishes, they could not be worse.

The north-east rains are already in. Last night the thunder was growling in that quarter, and this afternoon there was more of it, with gathering rain-clouds which in time crept high enough to give us a small benefit. Our attitude towards this visitant is like that of the æsthetic maiden listening to the recitation of verses by a poet of her own school, as once depicted in *Punch*, and her intense cry is ours, for "more, and more and more."

In these days of Government-doctored coolies and medical inspectors, the pharmacopœia of the planter has shrunk in proportion almost to his diminished revenues. In some cases it has all but reached the vanishing point. There is still abroad however a strong belief in castor oil, and to that as a "cure-all" many of us cling. Whether it be administered to the patient in a glass, a coconut shell, or direct from the bottle or gallon tin, is neither here nor there. Its presence in the planter's office, surrounded by a beggarly display of empty medicine bottles, is as pathetic a sight as the last heirloom of a fallen family, for it is the link which unites us to a prosperous past. In that golden age, one never dreamt of a "cure-all," drugs were plentiful, whereas now we cannot afford them.

A planter who had run down in this way was visited by an ailing cooly. The cooly had been to the Coast for some time, had returned, and came to the bungalow to be cured of an ailment, which he indefinitely described by "sogam illai." His master—kind-hearted soul—retired, produced his one unfailing remedy, and was about to administer it, when the Tamil, with the recollections of the late past flashing through his mind, and which broke into voiceless speech in the expression of his face, said with a deprecatory wave of the hand, "Is it the castor oil, my master! It is unnecessary." Then he sadly retired.

When that planter told that tale to me, the recollection of the inflections of voice, the alteration of expression, and the whole surroundings—which can't be put upon paper although it can be acted—brought tears into his eyes as well as into mine. It was absurdly comic.

Pepper Corn.

DR. TRIMEN ON *HELOPELTIS ANTONII*.

What with their involuntary education in the life history of *Hemileia vastatrix*, the planters of Ceylon ought to know something of the mysteries of mycology; while their knowledge of entomology ought to be much more complete, from their experience of brown or black bug, cockchafer beetles and their grubs, brown and white, and in these latter days thrips, red spider, and though last not least of insect pests, *Helopeltis Antonii*. Amongst the Faunæ of the island, the coffee rat is better known on coffee estates than loved, except by Ramasami, who loves the rodents to the extent of eating them, Dr. Trimen's report which we publish today reveals a good deal of the life history of *Helopeltis Antonii*, but it seems evident that the aid of the magnesium light and powerful microscopes could be well called into requisition for the capture of the "immature" but destructive "cusses" at night. For, Dr. Trimen's only remedy is one which can be formulated as "Catch them and kill them." We should add after what we saw on Mr. Kerkhoven's tea estate in Java, "Give them to the dogs to eat." The remedy now recommended differs only in one respect from that of the old Scotch doctor for the killing of fleas. He gave a phial full of a mixture calculated to kill the insects, and to the question "How is it to be applied?" answered "Catch them by the neck and pour it down their throats." Dr. Trimen's prescription is simpler, being limited to the mechanical operation and dispensing with the *physic*-al. We sincerely trust the catching and killing process may be successful in banishing from our midst what seems to be a recent introduction. The pestiferous insect has done mischief enough on cacao, but it would be a far more serious calamity, were it to attack and injure our tea as it has done in Java and India.

Royal Botanic Gardens, Peradeniya, 9th September 1884
No. 43.

The Hon. the Colonial Secretary, Colombo.

Sir,—With reference to my letter No. 33 of 21st June last and in further reply to your No. 50 of 18th June, I have the honor to inform you that I have made an examination into the nature of the insect-pest affecting cacao on the estates referred to in your letter.

1. I may say at once that the enquiry has satisfied me that the brief remarks I ventured to make on this "blight" in my last Annual Report (pp. 12-13) are correct. So far as my observations have gone at present, I am of opinion that the only insect which seriously damages cacao in the manner under consideration is the *Helopeltis Antonii*.

2. Cacao is indeed subject to the attacks of a large number of different insects, and appears especially attractive to those of the large groups of sucking insects known to entomologists as *Hemiptera* and *Homoptera*, and including besides the usually larger insects known as true bugs (*Coriside*, &c.) the *Cercopidæ* or Leaf Hoppers, the *Aphidæ* or Plant lice and the *Coccidæ* or Scale Bugs. All of these tribes contribute species which suck the juices of the cacao tree, but I have no reason to believe that serious injury is effected by any one of them. In the case, however, of a large increase in numbers of any, they might become formidable, and this appears to have happened to some extent on one estate, where multitudes of a minute but remarkable species of *Thrips* (closely allied to the Hemiptera) have done some damage to adult leaves checking their nutrition by numerous minute punctures and the discharge of their copious brown excreta, and so causing them to shrivel and fall before their time.

3. *Helopeltis* itself belongs to the true *Hemiptera*, being a member of the tribe *Cuspidæ* all of which are destructive to plants (one especially so to raspberry fruits) and are partly characterized by their comparatively active running habits of the genus, several species have been described by naturalists of which the present insect *H. Antonii* Lynt, is the best known. In the adult state this can scarcely be mistaken for any other insect, and may be recognized by the following description. The narrow body is less than $\frac{1}{4}$ inch (6 mm.) in length, but the greyish wings project beyond the abdomen and thus increase the length to nearly $\frac{1}{3}$ inch (8 mm.); the thorax is brownish-red in colour and ends in a slender red neck, from its centre arises the singular erect rigid pin-like process which gives the genus its scientific name (*hilos*—a nail). The head is small and black, and a characteristic feature are the antennæ quite $\frac{3}{8}$ inch (10 mm.) long spreading, 4-jointed, and curved. On turning the insect over, the abdomen is seen to be black, but in the female this is crossed about the middle by a broad band of white. The formidable beak or proboscis, fully 2 mm. long, can be seen beneath the thorax, to which when not in use it is pressed. The insect is long-legged and active and can fly well, but so far as I have seen does not make any long flights.

4. Before arriving at the imago state, the *Helopeltis* passes through several stages, but the changes (as in all the bugs) are not so complete as in most insects. When first hatched it is about 1-24th inch (say 1 mm.) long, pale yellowish olive in colour and semi-transparent, the eyes and some internal parts showing red. During its progress through the larval stage it sheds its skin several times, and the little empty sloughs are commonly found on the cacao. The olive colour is maintained through these changes, and the insect is easily recognized by the thoracic spike which is soon developed, the long antennæ, and the long legs which raise the body well off the surface; the abdomen is soft and pointed and turned up at the end. Rudimentary wings are present in the pupal stage but are not matured for use until the final change from this to the perfect insect. Though thus unable to fly, these immature creatures run about pretty briskly and their appearance is decidedly ant-like; apparently their whole existence is passed on the cacao plant where they were born.

5. I regret that my opportunities and leisure have not permitted me to trace out the whole life history of the insect. I do not know the time occupied from egg to imago nor how long the latter lives. I find that the female contains from 8 to 12 eggs, large for the size of the insect, and of a peculiar long flask shaped form provided at the truncate end with two filaments half its length. I have not succeeded in seeing the actual deposition of the egg, but I have detected two *in situ*, one attached to a punctured cavity in the leaf-stalk and the other in the tender shoot at the foot of a leaf-stalk; these were milk white with a tough skin. After a careful search I have not discovered more than these two, and my knowledge on the point is thus very defective; so far as it goes it corresponds with that of Van Gorkom in Java who says that (in *Cinchona*) the eggs are laid in the ends of twigs and in leaf-stalks but are quite hidden and very difficult to find.

6. The little insects commence to suck the plant at once, and they continue to do so throughout their lives. Apparently they especially feed at night, and the amount of injury a single one is capable of effecting can be seen by any one who will place one in a cage with a fresh shoot for a night and examine the shoot in the morning. The underside of the mid-ribs of the very young leaves is also a favorite position for the punctures. It may be presumed that the perfect female insect does some damage also by the deposition of the eggs.

7. The nature of the injury effected on the cacao is primarily a direct loss of sap. This nutritive fluid is drawn out of the delicate tissues of the newly formed shoots and leaves by the sucking action of the long beak of the insect. The immediate result is a collapse of the cells; they become shrunken and brown, and the apparent external effect is a depressed or sunken circular, or oval brownish stain at the position of every puncture. These are often in such proximity that the stains coalesce, with the result that the whole shoot is mottled with brown blotches of irregular form. The injured tissues soon die and are found after a while to have become black and rotten. A hindrance to the passage of the sap up the shoot occurs, the tips are seen to fail and droop, and the leaves to become puckered and stunted and irregular growth is all that is made. In worse cases the shoot withers away at the tip and the whole "dies back" to a greater or less distance. The tree soon endeavours to put out a fresh crop of shoots, and if these be again attacked, they share the same fate. At length after repeated attacks the smaller woody branches also die and only the main branches remain.

8. It was this "dying back" that first attracted the attention of the superintendent of the estates in question in Oct. 1883; and in December he forwarded to me some of the affected shoots for an opinion, being himself under the impression that the trees were "cankered." I at once informed him that the injury was due to a sucking bug. Since that time many successive crops of young shoots have been produced and destroyed, and though a watch was kept for insects, none could be detected doing the mischief. One of the small leaf-hoppers common in cacao (allied to *aphrophora*, the "cuckoospit" of England) being the most abundant insect to be found, was fixed upon as the probable culprit and was supposed to effect his depredations at night.

9. On my first visit I found but few fresh shoots on the tree, owing to the prolonged drought, the bad effects of which were clearly apparent, but what there were in the area affected had mostly been attacked, were badly spotted and evidently doomed to "die back." Though I was convinced this was the work of *Helopeltis*, yet a careful search with the superintendent revealed but a very few of them (in several stages), though insects of various other kinds, including the suspected plant-hopper, were more numerous. The difficulty, however, of detecting the immature *Helopeltis* is well-known, so much so that both in Java and Assam as now here, it is difficult for planters to believe that such serious mischief is wrought by a foe so nearly invisible. I therefore requested the superintendent to initiate systematic catching of this insect, which he consented to do. The results obtained corroborated my belief that *Helopeltis* is really far more abundant than it appears to be. During the first two days, indeed, though six coolies went over 220 acres, only 311 specimens resulted; but so soon as the boys learned how to find the insect, the numbers increased. Thus by the end of ten days 2,011 had been bottled, and in the forty-one days ending with August 31st, as many as 25,000 individuals (the greater proportion being immature ones) had been captured and destroyed. I believe that the cause of the "disease" is no longer a matter of doubt in the mind of the superintendent.

10. With regard, however, to the actual condition of the cacao trees on these estates, I should not be fully carrying out your request, if I were to omit to express my conviction that the damage done by *Helopeltis* in this locality has been rendered considerably more serious by certain local circumstances. There is no occasion for me to insist further on the generally recognized need of shelter from wind in the cultivation of cacao, but I may say that a dry wind is much more destructive when it passes over tender shoots already debilitated and rendered flaccid by the abstraction of sap and the exhaustion of their tissues; such become quickly desiccated and destroyed. So too, a period of drought, such as has been experienced this year, will have a more disastrous effect under the same circumstances than under ordinary ones. And these adverse conditions have operated with unusual force on the estates under consideration from the following cause; a heavy shade of large trees which formerly covered them has been completely cleared away. Thus the cacao, accustomed to shade and shelter, was suddenly exposed to the full effects of sun and wind. I have elsewhere expressed the opinion that in the moister districts of Ceylon shade is not required for cacao and need not be supplied, but it is a different thing to suddenly deprive plants of conditions to which they have become accustomed, and especially so in a dry district. Moreover, shelter can never be dispensed with. Thus though I regard the attacks of the bug as the origin and source of the mischief, I cannot but believe, that the damage has been much aggravated by the exposure of the trees, after long protection to drying winds and sunshine.

11. As regards remedies, I have but one to recommend, that is to catch and destroy the insect. Nothing else that can be suggested is so direct and radical as this. The cooly boys employed should be instructed to go over the trees, one by one in order, carefully and exhaustively; the larvæ and pupæ of *Helopeltis* being unable to fly are caught easily enough when once seen, and even the perfect insects are not quick to escape. No doubt, a promised reward for the largest "bag" at the end of the day will stimulate the search. The superintendent of the estates to which this report refers is of opinion that the practice has been of very great benefit; and indeed it was evident on my last visit, that the latest "flush" of young shoots, brought out by recent very slight rains had passed through the critical period, and has "set" without much damage during the time that the systematic catching of *Helopeltis* was being pursued. If the attacks of this insect ceased, I believe that the trees would to a great extent recover. Thus experience here, so far as it goes, perfectly agrees with that in Java, where the attacks of *Helopeltis* on cinchona produce almost precisely the same effects as here on cacao. By constant watchfulness and the capture of all the individuals that can be detected, the pest has in the Government plantations been kept under and in some nearly abolished.

12. Did we possess more certainty as to the precise positions where the eggs are laid and a ready means of detecting their presence, a timely removal of the parts of the tender shoots affected before hatching had occurred could be confidently recommended. Unfortunately the first indications we get are the brown stains showing that the young *Helopeltis* is already at work. The investigation of this point is to be strongly recommended to those in a position for observing it.

13. I have said nothing as to the attacks made by *Helopeltis* on the *pods* of cacao. Their agency here is generally allowed by planters, for they are easily observed puncturing the pods; and the black spots produced by them are familiar to growers. Considerable loss of crop has occurred from the consequent drying up of the young fruit, but the results to the tree are far less serious than when the insect directs its attention to the young shoots. I am, however, by no means sure that other sucking bugs besides *Helopeltis* may not be able to cause the black spots seen on the pod. Nor have I definitely alluded to the pest as it presents itself on other estates in different parts of the planting districts. This appears to be the less necessary, as a comprehensive report on the subject has been recently drawn up by a competent sub-committee of the Planters' Association who have also gone fully into the questions connected with the influence of soil, exposure and cultivation. This report I have been permitted to read, and I agree generally with a large portion of it.

14. As regards the future, I think our experience as yet is too brief to afford much ground for prediction. If, as I suspect to be the case, *H. Antonii* be a recent importation to Ceylon, it may be expected to increase. It is, however, confidently asserted by some observant persons that they have known the insect here for some years, and it appears to be a fact that pods were observed to be spotted in the way effected by this bug fully four or five years ago. The first living specimens seen by me were taken off cacao in June last year and the insect had then been noticed for a few months. I may add as bearing on the question that Mr. Moens of Java, when visiting our cinchona plantations in September 1880, constantly expressed his surprize at the absence here of *Helopeltis*, for which he was always looking out; also that the late Dr. Thwaites—whose knowledge of Ceylon insects was probably unequalled—declared, when I showed him examples from Java in 1881, that the species was certainly not a native of this island. But, whether exotic or native, its detection here is quite recent and cannot be regarded as of slight importance. *Helopeltis* is a formidable insect, it has, I regret to say, already commenced to attack our cinchona, and there are rumours (not, I trust, corroborated) of its having been seen on tea. It is, however, at present very local and does not appear to be spreading. We may hope that this may remain its character in Ceylon, but we cannot feel any confidence that such will be the case. It *may* be otherwise, and, with that possibility before us, it is earnestly to be desired that all who have the opportunity will search for and destroy *Helopeltis* wherever it exists and while it is yet in small numbers.

15. As much interest is being taken in the subject of this letter, I have to request that it may be made public at as early a date as possible.—I am, &c.,

(Signed) Henry Trimen, *Director*.

MACHINE AND HAND MADE TEA.

There seems no good reason for reviving the controversy about the comparative *staying* powers of hand and machine made teas: simply because one agent of one proprietor has raised the question. There is no more chance now of machinery being laid aside, in favour of the primitive method, slow, laborious, expensive and too frequently uncertain as that method was, than there is of steamships being shelved in favour of those dependant on sails and winds for their progress. There is no doubt, that, by means of unremitting care and attention on the part of the superintendent aided by a staff of well-trained tea-makers, very superior leaf can be turned out by the use of charcoal-fed choolas. But there can be as little question that teas of equal quality and of steadier quality all round (neither under-fired nor burnt) can be turned out by machinery and at a largely decreased cost. If machine-made teas have, in comparison, ever shown greater tendency to "go off," that has been owing, certainly, to imperfect drying, especially in the final process before packing. But all complaints of the kind had ceased, until the single broker of a single Ceylon proprietor stirred the question for no sufficient reason apparent to anyone.

MARIAWATTE AND ITS YIELD OF TEA PER ACRE.

It is stated, that, from the area of 100 acres in full bearing on this estate, tea equal to 900 lb. per acre has been already gathered, but that, as pruning (which had been delayed) has now been taken in hand, the yield for the year will not exceed 1,000 lb. per acre, instead of the 1,200 lb. mentioned by rumour. As in Chittagong previously, so now in the Gampola valley, 1,000 lb. per acre will be secured by means of a liberal application of manure. Taking this into consideration, the estimate of 700 lb. per acre for lowcountry estates, opened in virgin forest but unmanured, is what ought to be expected. We suppose Mariawatte will be ranked as a lowcountry estate, seeing that its elevation is only about 1,600 feet above sea-level, the altitude of the railway station close by being 1,573. The tea estate stands on the site of the first regular coffee estate opened in Ceylon, but the place had been long enough in "chena" to allow of considerable recuperation of soil. The climate, as regards copious rainfall alternating with genial heat, is all that could be desired. Add to this that the place has special facilities for procuring and applying manure, and a case is made out for the exceptional yield obtained. The result is a grand one, even allowing for manuring; but we see no reason to modify the figures for averages of 700 lb. per acre on lowcountry estates (sea-level to 2,500 feet) and 400 to 500 at higher elevations.

THE PURE WINES OF AUSTRALIA.

To those who drink wine—and they are still many in the face of temperance and tea agitation—it is of great importance that the beverages they partake of should be pure and unsophisticated and not doctored and drugged and deteriorated by the addition of more alcohol than nature provides should be developed in the process of grape fermentation. The vast majority of the Australian wines are good and pure, and all that is necessary to render them acceptable is that they should be old enough to have lost all trace of fusel oil and to have acquired the full and delicate bouquet, so much desiderated by connaisseurs in wine. Samples of such pure wines, five years in bottle at the least, have been brought to Colombo by an agent of Messrs. Caldwell & Co., of 114, Collins Street West, Melbourne. They include clarets which tastere, not knowing the origin of the wines, have frequently preferred to the best French clarets at three times the price. If there is any difference it is that the Victorian claret is less acid than the wines imported from Bordeaux. There is a port, so called, which ought in the case of invalids and for sacramental purposes, to supersede the generally fiery and manufactured wines for which Portugal has been so long famed. There is also an excellent red Hermitage and a sweet Muscat, a perfect ladies' wine. Next to the clarets, however, opinion is likely to incline in favour of the wines called Chablis and Hochheimer, the latter slightly stronger and with a more pronounced bitter than the former. There are other wines all good in their way: Verdeilho or Madeira, Tokay, Reisling (recommended by a medical committee), Constantia, Shiraz, Frontignac and Cabinet (recommended by a medical committee for young people, where wine as a tonic may be prescribed). But we should think that the run would be specially on the clarets, of which there are three qualities, and on the Chablis and hocks as white wines. If something more approaching sherry is wanted, there is the Reisling which is somewhat warmer and fuller than the Chablis and hocks. Wine *cannot* be made without the fermenting process ("new wine must not be put into old skins"), and during fermentation a certain amount of alcohol must be developed. But, if wines with no higher degree of alcohol had ever been used than characterizes these Australian wines, we believe intemperance would never have made such headway as to demand the stringent remedy of total abstinence. We by no means desire those who do not use wine, either on principles of high expediency or because they can "get along" very well without it, to become wine-bibbers. But to the large class who believe that good wine in moderation is a good thing, we can recommend the pure, light Victorian wines.

CEYLON AND ITS PLANTING INDUSTRIES.

TO THE EDITOR OF THE TIMES.

Sir,—Ceylon and its planters have been several times referred to in the discussion in the *Times* on the prospects of sugar cultivation in the West Indies, and perhaps a brief *résumé* of the experience gained in the Eastern colony during a series of trying years may be of some interest and of service to planters elsewhere.

It is pretty well-known how in the course of 40 years, from 1837 onwards, Ceylon rose from being a mere military dependency (involving a considerable annual burden to the mother country) to the position of the first and wealthiest of British Crown colonies. During that period its population, revenue, and trade so steadily advanced that they well-nigh excelled those of all the West Indian colonies put together. The change was due almost entirely to the development of coffee-planting, which gave in the heyday of prosperity as much in one year as £5,000,000 sterling worth into the markets of the world, chiefly through London. Other branches of agriculture prospered and advanced during those 40 years such as palm tree, cinnamon and rice cultivation in the low country—coffee being grown on the hills—in the hands of the Sinhalese and Tamils. But it was through the capital introduced and the revenue created by coffee that the natives were enabled to extend their groves of coconut and palmyra palms, and that the Government could devote large sums to the restoration and construction of irrigation works, more particularly in supplying village sluices and tanks where the people were ready to make use of them.

So far as European colonists were concerned coffee-planting almost exclusively claimed their attention, and many of the Sinhalese also embarked in this enterprise. While it continued profitable the counsels of those who advocated the cultivation of other products was treated as so much idle breath. Theoretically it was shown many years ago that the climate and much of the soil of Ceylon were better suited for tea than coffee; but still the felling and clearing of the most beautiful and varied tropical forests in the world went on until from 400 to 500 square miles of country were covered with the one shrub, *Coffea Arabica*, carefully planted, and scientifically pruned—topped at the height of an average gooseberry bush. Nature was, however, preparing the punishment of a gross violation of her laws—one paralleled by the would-be dependence of the Irish 40 years ago on potatoes, by the cultivation in other countries of too wide and unbroken an area of wheat, or of the vine. The penalty in Ceylon was first manifested in 1869, in a minute fungus on the leaf, parallel more or less to the *oïdium* in the vine, rust in wheat, and the potato disease. For some seven or eight years not much was thought of it, save as an inducement to more liberal, careful cultivation; but the scientists called in to investigate showed that little or no practical check could be offered, and within 15 years, to make a long story short, the minute, despised fungus had swept 100,000 acres of coffee cultivation out of existence—the poorly cultivated native gardens and poorer plantations being naturally the first to be abandoned. At the same time the export of the coffee bean fell last year to one-fourth the *maximum* of 1,000,000 cwt. Here was certainly a grave national misfortune overtaking a body of industrious men who had been the mainstay of a country's prosperity, and, moreover, their difficulties were aggravated by an extraordinary development of coffee production in Brazil. This was due to the interior of that South American Empire being rapidly opened up by railways made out of borrowed money; the labour, at the same time, used in opening fresh coffee plantations being slave. Such competition might be deemed unfair—more particularly as it has taken 12 years' agitation in Ceylon to secure an extension of less than 100 miles of railway from the Colonial Office; but, in place of looking to the Government for factitious aid, the Ceylon planters ten years ago turned their attention to new products with all the energy and intelligence for which they are famous beyond any other tropical cultivators.

In many cases, of course, the new products, such as cinchona, tea, cacao (chocolate), and rubber, were experimented with as supplementary to the 175,000 acres of select coffee still maintained in cultivation, and let it be noted that in interspersing his coffee fields with cinchona and rubber trees, in planting belts or boundaries of such, or areas of reserve in tea, the planter was using one of the best means of checking the free dissemination of the fungus (*hemileia vastatrix*). As a consequence possibly, or perhaps the virulence of this pest is abating, during the current season Ceylon is giving an improved crop of coffee, the export being in excess of last year's by probably 100,000 cwt.

At the same time, the productions of tea and cinchona bark have become established and important industries. The export of the latter this year will probably be equal to 10,000,000 lb. against the beginning in 1869 with 28 oz. Nor is it expected that South America can ever again compete with the East—Ceylon, India, and Java—in the production of the invaluable febrifuge.

Again, it is acknowledged on all hands now that Ceylon is better adapted to become a great tea-producing country than ever it was to lead with coffee. Situated in the path

way of the two monsoons, with an ample and well-distributed rainfall, in a most forcing climate, Ceylon is a perfect paradise for leaf crops. Fruit is more uncertain, and even in the best days of coffee great uncertainty often prevailed during the six weeks or two months of a blossoming season, when too much or two little rain often destroyed the chance of a due return for a whole year's labour. Coffee, too, could only be cultivated within certain limited positions, from 2,500 up to 5,000 feet above sea-level; whereas tea flourishes from sea-level to 6,000 feet and over. The tea shrub, in fact, is one of the hardiest of plants growing in the open-air at Washington, United States, in New Zealand, &c. But the great advantage possessed by Ceylon and India for tea is in cheap, suitable labour for the work of cultivation, leaf plucking, and preparing. The little island of Ceylon, as now opened up by railways and splendid roads, offers great advantages over most Indian districts for tea production. From both countries the tea supplied is of a pure, high quality. China teas have, in many cases, deteriorated of recent years, while the Japanese "greens," chiefly sent to America, are nearly all adulterated. I may, in passing, say that should the war now begun between France and China interrupt the tea trade or production in the Far East there is no place where a return can be so expeditiously got for the investment of capital in tea as in Ceylon. There is a wide extent of land available for tea, at an upset price of 10 rupees (16s.) per acre freehold, and a good crop of leaf can be had within three years of the planting. Assam planters who visit Ceylon are loud in their praise of what they see in the growth of our tea, our fine climate, unequalled roads, good supply of labour, &c. The progress already made in the tea industry may be seen from the figures appended.

The cacao, or chocolate-yielding fruit tree, is another new article of cultivation which has been successfully established in several districts, the Ceylon product from this plant being pronounced already in Mincing-lane to be equal to the very finest received from Trinidad or South America.

Indiarubber yielding trees of various descriptions have, during the past few years, been extensively planted in Ceylon, but the industry is still purely experimental, although good samples have been seen in the London market.

In fibres there ought by and bye to be a great development of industry and trade in Ceylon, and, indeed, "capital" is the only element wanted to secure rapid progress in all the branches referred to. The fall of the Oriental Bank has reacted disastrously, rendering money very scarce for the poor but industrious planter, while, again, the credit of the colony has been damaged in many places through the non-success for many years and the final collapse of the Ceylon (but more properly Mauritius Company (Limited). It is at this time, and in view of the absolute scarcity of capital and depression of credit, that many planters in Ceylon think their industries in "new products" should receive some official support; but they have no idea of interfering with the great principles of free trade or of making a grievance out of the advantage possessed by the slave-owning planters of Brazil.

It is a matter for congratulation that from the very beginning the Ceylon planting enterprise has been based on a system of free labour, and that the produces are so universally appreciated and beneficial as coffee, tea, quinine, chocolate, cinnamon, palm oil, &c. There is every reason to feel assured of a profitable return for money judiciously invested in these "new products" in Ceylon, and the much-tried sugar-planters of the West Indies cannot do better than make experiments in the same direction, although, I am free to admit, the comparative scarcity and dearness of their labour places them at a heavy disadvantage.—I am, Sir, &c.,

J. FERGUSON, of the *Ceylon Observer* and *Tropical Agriculturist*.

Royal Colonial Institute, 15, Strand, Aug. 23rd.

The following are statistics of some of the planting industries in Ceylon:—

Coffee.—1837—2,500 acres cultivated; exported about 10,000 cwt. 1847—45,000 acres cultivated; exported about 200,000 cwt. 1857—85,000 acres cultivated; exported about 450,000 cwt. 1867—168,000 acres cultivated; exported about 868,000 cwt. 1877—272,000 acres cultivated; exported about 976,000 cwt. 1883—174,000 acres cultivated; exported about 265,000 cwt. 1884 is expected to show an export of over 350,000 cwt. of coffee—a welcome revival.

Tea.—The export began with 482 lb. in season 1875-6, the export rose to 81,595 lb. in season 1878-9, the export rose to 1,522,882 lb. in season 1882-3.

The current season will probably show an export in excess of two million pounds, and when the 35,000 acres of tea now planted are in full bearing, in 1887-8, the season's shipments ought to be equal to 10 million pounds. Eventually it is estimated Ceylon should have 150,000 acres under tea, and an annual export of 60 million pounds and upwards. It depends on home capitalists very much how soon this result may be realized.

Cocoa.—The export of cocoa (as it is called in the market) began with 10 cwt. in 1878, and last year it was 4,000 cwt. while for the current year it is likely to reach 10,000 cwt.

Cinchona bark began with an export of 28 ounces in 1869, rose to 507,000 lb. in 1879, and was last season equal to seven million pounds, while for 1884 the return is likely to exceed 10 millions.

Palm trees and Cinnamon.—Of the products of its palm trees and cinnamon bushes, cultivated chiefly by native owners, Ceylon now sends an annual value of from £800,000 to a million sterling into the markets of the world, against less then one-fifth of this value 30 years ago.

TEA COOLIES IN ASSAM.

Putting the matter on the lowest ground, the coolie is a valuable chattel, which costs the planter a considerable amount of money. The object of tea-planting is to make money; and the best, the only way to success, is to keep the indispensable coolie in good health, and in good humour, so as to get him to work cheerfully and well. Accordingly, any visitor to a tea garden, who has the curiosity to go among the coolies' lines to see and judge for himself, will find that they are comfortably lodged—much better than the average coolie would be in his own *gaon*. Then, they have skilled medical attendance provided for them, and hospital accommodation and comforts such as they could get only in a large town in the plains. Nevertheless, the plantation death-rate is certainly high. The reason is to be found in the nature of the climate, and the unsuitability of many of the coolies imported to stand it. The great majority of those who die on the gardens succumb under the process of acclimatising. The best coolies for the Assam tea gardens are those taken from the low-lying jungle-growing tracts of Bengal, where somewhat similar climatic conditions prevail to those found in Assam during the rains,—at once the unhealthiest and the busiest season, when the coolies are liable to contract ailments which render them disinclined to work, and when work is most required. These Bengalees are not equal in physique to many of the coolies imported from the North-West and from the highlands of Chota Nagpore; but they are of far more use on the gardens. The "North-Westers," besides not being constitutionally suited to the climate, have to change their diet, and do not thrive so well on rice as on the more substantial grain foods to which they have been accustomed. Further, they are penurious folk, and will deny themselves proper quantities of such food as they can obtain for the pleasure of saving a few annas a month extra. Consequently they lose their strength, and speedily fall victims to the climate, to battle successfully against which requires all their stamina. Then, in spite of all precautions—in the face of the Inland Emigration Act with its elaborate provisions for registering, medical examination, etc.—a very large number of coolies are sent into Assam and Cachar, who are utterly unfit for work there or anywhere else, and who simply go to swell the bill of mortality. Planters cannot help themselves. They are necessarily to a great extent in the hands of the contractors and agents acting at a distance.—*Indian Daily News.*

"JÂT" OF TEA.

We must not condemn all China tea as bad. There is surely one simple rule by which to choose plants of good jât:—Best hybrid Assam are distinguished by largeness of leaves, markedly serrated on the edges, and the colour never dark as is often the case in China, but of a rich green, brightened with a dash of golden yellow. Tea, in China itself, varies according to locality and climate. We once read of some enormous tea trees with leaves large in proportion, in the neighbourhood of a Chinese dwelling, to which the family tradition ascribed an age of five centuries! We are unable at this moment to refer to the work in which we found this notice, but we believe it was in a second record of travel by Cooper, the explorer of China. From his first book, "Travels of a Pioneer of Commerce," we quote the following passages:—

The district of Ya-tzow is extremely rich in minerals. Coal, iron, lead, and copper are very abundant; and it is principally from this district that Sz-chuan is supplied with metals, especially steel and copper.

But the greatest source of wealth to the city and surrounding district is the brick tea, which gives employment to thousands engaged in the manufacture and portage of tea from Ya-tzow to Ta-tsian-loo. The tree from which this peculiar kind of tea is manufactured grows chiefly along the banks of the Ya-ho, and, unlike that which produces the tea exported to Europe, is a tall tree, often fifteen feet high with a large and coarse leaf. Little care is bestowed on the cultivation. It is often planted along the borders of fields and homesteads, each farmer gathering his small crop of tea, and finding a ready sale for it in Ya-tzow to merchants who pay the Government enormous sums for the monopoly.

I never had an opportunity of witnessing the process by which the tea is made into the exceedingly hard bricks which find their way to Thibet; and so great is the jealousy with which the monopoly is guarded, that even bribes failed to procure permission to enter the warehouses where the tea is packed for exportation. I am indebted to the landlord of the hotel where I lodged during both my visits, for the following imperfect description. The first quality is gathered in June and July, or shortly after the commencement of the summer rains in the end of May, when the leaf is about an inch long. When gathered, it is spread in the sun till slightly withered, and then rolled with the hand until moist from the exudation of the sap. In this state it is rolled into balls about the size of a large tea cup, and laid up till it ferments. It is then ready for the wooden brick-moulds, which are made with the ends movable, and fastened by pegs. The moulds, when filled, are dried over charcoal fires until the tea is baked into a tough solid mass. When taken from the moulds, the bricks are ready for delivery to the merchants of Ya-tzow. By them the bricks are enveloped in peculiar yellow paper covers, bearing a government stamp and the trade-mark of the exporter, and are packed in baskets four feet long, made of thin strips of bamboo. The bricks thus packed form what is called a basket of tea, weighing about twenty pounds. These baskets are carried by coolies to Ta-tsian-loo, a distance of two hundred miles, where they are carefully covered with green hide, as a protection against wet, and are then ready for exportation to Lhássa, and the countries to the west of it, where this particular kind of brick tea is principally consumed, selling for about fifteen taels per basket, or four shillings and eightpence per pound.

The second quality, which consists of the older and yellower leaves, is manufactured in the same manner, and exported principally to Lithang and Bathang, where it is sold at five taels per basket, or about one shilling and six pence per pound.

A third quality is made entirely of clippings, without the leaf, and resembles bricks of chopped twigs The manufacture of this kind differs from the others, rice-water being used to make the twigs adhere and retain the brick form. This quality is only used in Ta-tsian-loo and its immediate neighbourhood, selling for ninepence per pound.

The quantity of brick tea annually exported from Ya-tzow to Thibet has been roughly estimated at over six million pounds.

Again Mr. Cooper wrote:—

From the Fei-yue-ling mountains our road gradually descended through a more fertile country, with occasional patches of rice cultivation, and in two marches we arrived at the city of Ya-tzow-foo. So far I had retraced my steps, but as I intended to descend the Ya-ho, and visit Kia-ting-foo, instead of returning by Chen-tu, we here left the main highway, and followed the banks of the Ya-ho river for two days' journey, through a beautiful undulated country, devoted to tea cultivation, forming the district where the best brick-tea for Thibet is grown. The whole country formed a series of large gardens, without a single fence to divide the different plantations, and kept in the most scrupulous order, the trees, which stood about four feet high, being neatly trimmed, and planted in rows four feet apart. The numerous homesteads which were visible were surrounded with belts of large tea trees, growing to a height of twelve to fifteen feet.

It seems beyond question that tea found its way into China originally from Assam, a good many centuries ago now, and that the bush has deteriorated, either from severity of climate, careless cultivation or breeding in and in, until we see it, with small and often darkly-coloured leaves, a poor contrast to indigenous Assam or best Assam hybrid. The latter is the result of a cross between China and Assam, which is almost equal to indigenous Assam in luxuriance of yield and more robust, and therefore better suited for elevations above 2,500 or 3,000 feet.

ADVICE TO YOUNG CACAO-PLANTERS.

16th September 1884.

Land.—Cacao will grow while the plants are small from sea-level up to three thousand feet elevation, but the question is whether it will grow up to become a good bearing and lasting tree. 1st, we have some very fine lands with good shelter and rainfall where cacao will thrive without much assistance or attention by the cultivator; 2nd, we have lands which have a very good deep subsoil but the surface soil impoverished by former chenaing, coffee or other cultivation; 3rd, we have also lands, though good in substance, much exposed to the wind; 4th, we have shallow lands; 5th, there is land where the heat is great and the rainfall hardly sufficient for the growth and bearing of the cacao; 6th, we have lands with a very sandy soil. We may even in one estate find all the above various lands: though various, it remains for the planter, after he has got his lands, carefully to note all the quality of the soil, shade or shelter likely to be required, and then to have the land cleared accordingly, with shade or shelter or any unsuitable land left. On every estate a piece of jungle ought to be left for timber and manuring purposes: good new timber plants should be planted as old trees are removed. The decaying vegetable mould accumulating under the trees could be gathered as required and mixed with other manures for application to your cacao trees. Old, dead and useless trees, branches, &c., will do for firewood. The planter who can get lands possessing a good, deep, rich, stiff soil not exposed to wind, with ample rainfall, will have the least expenditure and get the most profit; at the same time cacao with careful attention can be grown profitably on all lands as above described, except on Nos. 4 and 6, which I would reserve in jungle or plant with grass for cattle or mana for manure.

Cultivation.—Having disposed of the land question we now come to the cultivation. On No. 1 land planting at stake, if shaded and no grub or other insects, destroy the plants will be very successful and

best, but for all the other lands I should make nurseries either in beds, pots, bamboos or baskets, selecting a stiff good soil for the same. I saw Mr. Drummond advised a poor soil for the nursery because the roots would not go deep. If after you dig up your nursery, take out all stones and roots, make it into beds, then beat the soil down you will get a strong healthy plant, and the root will not go down too deep. On no account use a sandy soil for a nursery: it will tend to give plants the black heart will attract more heat to the roots and cacao will not thrive in sandy soil unless it is always moist. Nurseries should always be shaded and well-watered. Should a nursery be attacked by insects, a dusting of sulphur, wood-ash, lime, or a mixture of the three, or, with a solution of kerosine oil or vasumba, water your plants This can he done in a nursery without much expense, but would be too expensive to go all over the estate. In good soil small plants can be planted out, but in poor soil I would prefer to let my plants grow up from 12 to 18 inches before planting them out. Great care should be taken in the selection of seed pods. There are said to be some 16 varieties of cacao already in Ceylon. Some say the yellow fruit is safe from insect attack. I have heard otherwise. At all events, the fruit of the large, dark, red, rough pods is a large oval seed, and, if well cured, will bring the best price, and the trees grow well. The seed should be planted with the part nearest the raceme down. You will often find the seed planted the wrong way, and that the roots will come up and then turn back into the soil, wanting strength to lift up the seed. The stem gets very large at the lower end, but very thin near the seed; it is then that the lower stem often gets black-hearted. If soil is left as dug over without pressing it down, it will be very difficult to transplant, even planting at stake the soil should always be well pressed down before seed is planted. The cacao plant thrives best in a stiff soil: in light loose soil, the soil will not keep together, and, if using Scowen's transplanter, the pressure you use to push out the plant will most likely double up, or otherwise injure the root, whereas in stiff soil no injury will happen to the plant. A good plan in making a nursery on new or old soil is to have the soil well-covered with some cut jungle, maana, &c.; when dry enough to burn same, then to dig the soil and make beds. All young plants like wood-ash, and the burn will kill any germs of fungi or eggs of insects. There is difference of opinion as regards the best size to plant out cacao: some say from 6 inches to 1 foot, and to plant out in June or July. I have planted out cacao plants from 6 inches in height to 3 feet in height at all times during the year, and have certainly had the least failures amongst the large plants. I do not consider it good to plant out cacao in rainy weather, as you might plant coffee or tea, as great care is required not to disturb the soil around the cacao plant in taking it out of the soil, carrying or planting it. To plant in very light rain is safe, but I consider it best to plant when there is no rain as long as your soil is damp, and you have mana or good leaves to shade the plant, especially so on steep land. On flat land the surface roots of the plant can be nearly level with surface of soil, but on steep land I would advise the surface roots of the plant to be 2 or 3 inches below old surface soil on lower part of hole and make a small outlet for water—after the plant has fairly grown 1 foot or so, then bring in soil from the sides and fill up the hole. You will protect the surface roots from the sun as well as from the weeders and wash.

Holing.—There is a great difference of opinion. Some planters make no holes but plant at stake with alavangas or forks; others make holes from one foot to two feet deep, and from one foot to two feet wide. Fifteen inches wide by two feet deep is now the size of holes mostly made. In steep land I would certainly advise deep holes slanting towards the hill. If you cut straight holes, the lower side roots will not have much soil to feed on. The plant planted in a hole cut slanting will, with a slight curve near the ground, become a straight tree above. You must always keep suckers from the plants but never pull them off, but always make your contract weeders cut them off. It is not necessary to keep a cacao estate weeded same as coffee: it can be treated somewhat like coconuts in the lowcountry, only keeping the ground clean in a 3-feet circle around the tree, taking out all jungle or large weeds from the balance.

(*To be continued.*)

CACAO CURING IN TRINIDAD.

Trinidad has for so long been famous for its cacao, that we never doubted that the art and mystery of curing the bean were, in that colony, perfectly understood. A long report in the *Port-of-Spain Gazette*, of a meeting of the Trinidad Agricultural Association, of a paper which was read by a Mr. W. S. Tucker and the discussion which followed, gives us a very different impression and convinces us that our planters in Ceylon must have the advantage in this matter. It seems that Mr. Tucker was compelled by circumstances to become a cacao-planter, and that, in his efforts at curing the bean, he encountered great difficulties in preventing mildew and the shrinkage and collapse of the bean, which ought, he said, when perfectly cured, to retain somewhat the shape of a pigeon's egg, the internal portion of the bean being, if anything, freer from moisture than the outside. He also found that beans of different varieties of cacao and of different sizes ought to be cured separately. Having met with much disheartening failure in his attempts to cure the beans by ordinary atmospheric influences, Mr. Tucker resorted to artificial dessication. It seems that the Cacao Planters' Association had ordered from Mr. Gibbs, manufacturer of the Gibbs & Barry Tea Drier, a machine on the same principle for the preparation of cacao beans. We may, in passing, and as a hint to cacao curers in Ceylon, say, that, in our opinion, they ought to have indented on the United States for a fruit evaporator, one of those machines which ere long will be tried in Ceylon in the roasting of tea leaves. Mr. Tucker tried Gibbs's machine, which, as we have stated, was on the same principle as the tea drier, a metal cylinder through which heat was driven by fanners. But, strange to say, considering that the tremendous heat of 700° Fahr. is obtained by the tea drier, the cacao machine failed from deficient temperature. The highest that could possibly be obtained by its means was 160°, and the beans, repeatedly inserted, came out merely warm instead of hot, and, according to Mr. Gibbs's directions, the beans were left to cool each time they came out of the cylinder, the effect of which Mr. Tucker denounced as very bad. As the real secret of curing seems to be that of so dispelling moisture from the soft fatty substance as to prevent either collapse of the swelled-out bean or the formation of mildew ending in rottenness, Mr. Tucker felt compelled to abandon the use of Gibbs's machine, and resort to one of his own invention. By means of this machine and the burning of wood-fuel, he obtained a heat of 300° to 400° Fahr., and so turned out his beans pigeon-egg-shaped and perfectly dessicated, so as not to be subjected to what poor Clerihew described as "eremacausis or decay." Mr. Tucker was about to proceed

to London to have a machine on his own principles properly constructed. But surely climate and other circumstances cannot differ so much in Trinidad as compared with Ceylon as to render a machine for artificial dessication necessary in the West Indian colony, while ordinary and simple appliances and atmospheric heat suffice here? Mr. Tucker stated that from 2s to 4s per lb. constituted the difference of price realized by his best prepared cacao as compared with the mildewed specimens, but we do not gather that any cacao prepared by the new machine had gone into the market. Mr. Tucker was rebuked by a Mr. Lange for his exaggerated references to mildew, in reality a fungus, as necessarily involving rottenness. Mr. Lange pointed out that mildew in cheese did not deter persons from eating it, and he also stated that when packets of prepared cacao, in the shape of chocolate, came back to Trinidad, a certain amount of mildew found underneath the paper wrappers was not deemed objectionable. So, a certain amount of mildew on the beans when they arrived in London did not greatly deteriorate the value of the article. The President, however, disagreed, saying that every bag was sampled and that mildew would cause a reduction in price. We have thus given what we believe to be the gist of Mr. Tucker's paper and the discussion, but, to leave no doubt in the minds of our readers specially interested in the matter, we quote Mr. Tucker's own description of what he deemed successful dessication :—

Mr. Tucker said he had altered it (the Gibbs Machine) by making a different machine altogether. There was not only this that he had overcome, but he also found that the cocoa would not dry properly; so as to be a properly inflated bean, it must not only pass through but must be kept continually in a hot place; it must be retained; the moment you took it out and condensation took place, as soon as it cooled, the bean collapsed—it was impossible to replace that fine round bean that you could make of it. Consequently it required to remain in this hot air a sufficient length of time or else it became inflated like a bladder and the outside would dry and break. Mr. Gibbs in his recommendation sent along with the machine stated that the cocoa should be taken out and cooled. It was not the thing at all. It should be so regulated that the machine could be constantly kept in motion at a certain temperature, and there the cocoa should remain until desiccation took place in the interior, or throughout the whole of the bean, so that there was, if anything, less humidity in the centre than externally. In his process he could not do what he called the "first desiccation." The cocoa remained there for two hours; it was then taken out of that desiccator and placed in one of lower temperature to be totally dried. There, so far as his experience went, it remained for about three hours. After that time you took the cocoa out and put it down on the floor and allowed it to cool. That inflation was maintained because the inside of the bean was already dried, or very nearly dried, and there it remained fixed, and the cocoa then cooled and the moment it was cool you put it back in the cylinder.

Mr. Lange: And what is the shape of the beans?

Mr. Tucker: Somewhat like a pigeon's egg, more or less inflated, and as I have said when gathered from mature, large, and old trees on the estate, these beans have formed magnificently.

Mr. Tucker made a great point of the pods being from well-matured trees and the pulp being thoroughly washed off.

Mr. Tucker's paper and the discussion on it occupy 6½ columns of the Trinidad paper, and we give the full report on page 339. We should like to know if the processes of preparation in Ceylon are effectual in clearing away all pulp from the beans; in expelling all moisture, so that no room is left for the formation of the fungus called mildew; and, finally, if the beans thus prepared preserve a nice plump shape. If there are defects in the simple process, and if artificial dessication is deemed beneficial, we should think the *Sirocco* or any other tea drier could be put into requisition. But we incline to think the American Fruit Evaporator would answer still better?

Jackson's New Tea Drier.—We have seen plans and sections of Mr. Jackson's newly-invented machine. There is a series of pipes, open to the exteroal air, which will be heated by a flue passing through them. The heated air in those pipes will be drawn upwards by a fan so as to pass through a series of three finely-perforated metal plates. The tea, fed in at the top into a hopper, will travel along the first plate and drop to the second; it will then travel over the surface of the second and fall on to the third; travelling over the third plate, the tea will be discharged completely dried without a single tray being brought into requisition. This ought greatly to diminish the proportion of broken tea and dust, and altogether the principles of the new machine look good and give promise of success. Jackson seems determined to add the best tea drier to the best pulper. There are to be two sizes: one to dry 150 lb. per hour; the other 300 lb. In the course of a few months one of the machines will be set up at Messrs. John Walker & Co.'s establishment, when planters will be able to judge for themselves as to its merits.

Indiarubber in Brazil.—The province of Amazonas in Brazil has shown so much liberality in emancipating all its slaves, that we are the more surprized at the petty narrowness displayed in the levying of heavy duties on plants and seeds exported. The legislation is too late to be of any use, but the paragraphs we quote show how important the trade in rubber is to the Province named after the great river, on the banks of which the trees from which the gum is extracted flourish. We quote from the *Rio News*:—

The province of Amazonas has passed a law prohibiting the tapping of rubber trees above 2½ metres from the ground, the tapping of young trees, or those less than 25 years old, and the injury or destruction of young trees. The fine is fixed at $1,000 for each infraction. A premium of $1,000 is offered for each thousand trees planted and cultivated, at two years of age, besides other favors to cultivators. To guard against foreign competition, an export duty of $500 is levied on every rubber plant, and $100 on every kilogramme of rubber seed exported.

The president of Amazonas sanctioned, on the 11th June, the law guaranteeing 6 per cent on a capital of $500,000 for manufacturing rubber goods.

The receipts of rubber at Pará, in kilogrammes, for the first six months of 1884 were 4,914,516, against 3,566,000 in 1883 and 4,130,000 in 1882.

The official figures for the fiscal year at the Pará custom-house give the total revenue at $10,531,201·650 against $10,707,135·607 in the previous year. This difference arises from the sharp fall in the value of rubber, which from $3,400-$4,300 in the first six months of 1883, gave for the same period in 1884 only an average value of $2350.

The budget law of the province of Amazonas authorizes the president to guarantee 7 per cent interest on a capital of £100,000 at par to a *credit foncier* bank, the funds of the bank to be employed in mortgages on property in the province; also to emit provincial bonds to the extent of $800,000, at 7 per cent interest and 1 per cent sinking fund, to establish a system of sewage in the city of Manáos; also to guarantee 7½ per cent on a capital of $200,000 to establish two mills for weaving cotton, or other textile substance and one for extracting indigo; also to guarantee 8 per cent. in gold to a tramway company for 33 years, proposals for which will be called for in the United States and Europe, horse or electric power to be used.

Correspondence.

To the Editor of the Ceylon Observer.

MR. THOMAS CHRISTY ON DRUGS.

155, Fenchurch Street, London, E.C., 13th Aug. 1884.

Dear Sir,—I am very glad you have called attention to the "Noyau, *Ipomœa dissecta.*" One of my correspondents in the West Indies urged upon me the value of this flavouring, and that almost all the noyau used in Europe was made with almond. He sent me over a liberal shipment, and I have endeavoured to circulate it amongst my friends both here and in France, and, I regret to say, with anything but satisfactory results. It has a beautiful flavour and is well worthy of attention.

As you take the *Pharmaceutical Journal*, I hope you will note the remarks made by Mr. Dyer of Kew upon "Bartung," the well-known *Plantago Ispaghula*, which is so largely used in Ceylon and India in cases of diarrhœa and which is largely used in this country. We have lately tried to have it coated with peppermint and sugar, but have not been successful in producing any improvement upon the natural drug. —I am, dear sir, yours faithfully, THOS. CHRISTY.

THE PRODUCTION OF RICE PER ACRE IN CEYLON

Sir,—With reference to your paragraph as to the production of rice per acre, I would point out that a crop of 1,500 lb of paddy is equivalent to about 50 bushels. In Ceylon it takes two bushels of paddy to sow an acre of land, so that, if the proportion is the same in India, the return is about 25-fold, not a very extravagant result, but which, I presume, is exceptional from its being noticed in the papers.

As regards the yield in Ceylon, you will find in the irrigation report a notice of a tract of land in the Matara district which regularly returns thirty-fold and twenty-fold is not an uncommon result in many parts of the island from *one crop*.

A correspondent in your columns last year I think reported the yield at Kandalay to be *fifty*-fold, but this was probably on *new* land.

In Mannar district it is said 100-fold is in a good year produced and I understand Baldæus mentions this as the return in those parts.*

Mr. Justice Dias, on his property, I believe, secures forty-fold. If I mistake not, he uses some manure. He has made many interesting experiments in paddy cultivation, and it would be very advantageous if he could be induced, to publish the result of his experience.

A word of cautions, however if necessary as to the use of the term "*fold*" in speaking of the return of paddy. It is *believed* (but I am not aware if there have been any careful experiments on this point) that a great deal too much seed is used in Ceylon, and that, as the sowing is consequently too thick, most of the superfluous seed is wasted and never comes to maturity. In parts of Southern India, economy of seed and more especially of water (where the means of irrigation are limited) is secured by first sowing in beds and transferring the plants to the fields.†

A smaller quantity of seed would in such cases, I am given to understand, suffice, without materially affecting the crop raised from any given area.

Possibly by this or by thinner sowing broadcast, or by restricting the seed used in any other method, experiment may show that the proportion of seed used may be safely reduced 50 per cent. without affecting the yield to be got out of any given area. In such case an acre of land might be sown with one bushel instead of the conventional two, and would ordinarily give a crop of say 20 bushels, but the crop would thus be spoken of as twenty instead of ten fold: thus there would be really no increased yield, only a saving of seed paddy. WIBADURALA.

* Baldæus's words are:—"...zijnde deze Landen vruchtbaar ende zeer bequaam om Rijs aan te teelen en te winnen, ja zoo overvloedigh, dat men dikmaals hondertfout aan eenen halm bevonden heeft," *i. e.*:—"... these lands being fruitful and very suitable for the cultivation and production of rice, in such quantity indeed, that often a hundredfold has been found on a stalk." The English "translation" of Baldæus does not qualify the statement in any way, but states that the rice "produces a hundredfold crop."—Ed.

† Universal in Java, we believe. Surely it is the best mode of culture, apart from economy of seed or water? —Ed.

GATHERING CROPS OF CARDAMOMS.

Sir,—Can any of your readers inform me whether in gathering a crop of Malabar cardamoms they have found it advisable to leave the racemes on, or to cut them off when the crop is mature, in order that they may bear again? Also whether racemes *do* bear again, and, if they do so, for how long? In fact the question is: Are racemes capable of producing fruit more than once? YELLUCKI.

CACAO IN JOHORE.

Pingerorg Estate, Johore, August 20th, 1884.

Dear Sir,—In a letter from a Ceylon planter received last mail he asked me to write you my experience of cacao planting here since I left Ceylon nearly five years ago

When I arrived here I made up my mind to fell my first 100 acres for cacao in jungle shade, which I did; but I was so disappointed at the slow growth of that in shade compared to a few acres in the open that I determined to fell the jungle shade all but 35 acres, which I kept on the most exposed part of the estate. I planted up all the part that I felled with *Albizzia Molluccana* and quincunxed this with dadap, fearing the failure of either. I was charmed with the *Albizzia Molluccana* at first. It grew rapidly and made a beautiful shade tree to look at: but at about 1½ year old I noticed the cacao trees all round it looking thin and miserable, and no wonder, for the ground was one mass of roots from this curse of a tree, so I ringed them all and trusted to the dadap But this, which I believe to be the best of all shade trees, is eaten off by pith-worms as fast as it grows, and I have had to go in for other shade trees, *madre de cacao*, which is also an erythrina, and *mindi*, another tree used in Java. All this will show you that I am convinced I must have shade for my cacao. The 35 acres in shade is as fine a piece of cacao as one could wish for, though it is the poorest and most exposed soil I have got. in it the insects give me little or no trouble. I think that as with grass, which is said by farmers not to be sweet in shade, so it is with the cacao leaves: at all events wherever I have cacao in shade the insects do it no harm to speak of, though the young leaves look just as soft and tender as those out of it. I have just read "P. F. L."'s letter to the local "Times" with reference to Mr. Jardine's, and it makes me rather disinclined to write, fearing such another snorter. I have got some 400 or 500 Carácas plants here (seed from Henaratgoda), and I wrote to one of my partners in Singapore more than six months ago telling him that the sap-sucking insect, which does me so much harm on the other cacao, did no damage to the Carácas, and I asked him to get me more seed: this certainly agrees with Mr. Jardine. The fly that troubles me here is also a sap-sucker, but it is a big sort of bug and has a very strong smell; my weeders

all carry bottles and bring me thousands of them. There are other insects that eat Carácas cacao leaves, such as the ladybird and grasshopper: but I do not fear them at all.

Cacao planted in forest shade has done well in every place that I have seen it in Johore, but I would recommend anyone planting in forest shade to dig round the young trees every six months or so to keep the roots as much back from the cacao as possible till they are a couple of years old, and then they seem to get on well with nearly every tree. Johore is going ahead now with Liberian coffee, and there is no doubt that it grows well here. but most of what has been planted by the Malays about Johore Bahru (the capital) is in lalang land, and will of course have to be kept manured after the first crop or so. It could not possibly look better than it does at present, and Johore can supply enough manure for the acreage at present in cultivation about the town.

I am making an experiment on a picked tree in the Maharaja's garden which I have had fenced in. On 27th July I picked cherry off it which gave me four catties of dry parchment coffee, and this day week I received cherry from the same tree which has given me 4½ catties of dry parchment coffee, and I believe that this tree will give from 10 to 12 catties within the year. Of course this is an unusually good tree, but there are hundreds as good as it in H. H.'s garden, and I did not go 50 yards before I told the gardener which tree I wanted to experiment on. This tree is as healthy as it possibly could be, and has had no manure for seven months, when it had a basket of cattle. When I go into Singapore I constantly go out to see Mr. Chasseriau, who is going to plant up all his tapioca estate with Liberian coffee; he has already done over 100 acres, and such a magnificent sheet of young coffee or a more creditable piece of work I have never seen, and he has grand facilities for manuring. I have now got 500 acres of sago planted, of which 150 acres are now over two years old. It is certainly a cheap thing to plant, but anyone who wants to do it with success and get a good even estate will find that they have more to do than stick the plants in and keep out the pigs. Sago plants when young grow slowly, and the grass and young jungle growth must be cleared for three feet all round them for a couple of years. I estimated my upkeep to cost one man per acre per month. It always raises my heart to walk through the sago estate, but it is a long time to look forward to.

I look back on my Ceylon days with pleasure, and hope soon to hear of good times there again.
—Yours faithfully, W. W. B.

TEA LEAVES AND TEA STUMPS.

Pussellawa, 21st August 1884.

DEAR SIR.—By this tapal I am sending you a tea leaf which caught my eye this morning. It was growing on a tree which was put out as a stump last October, and, though inferior in size, perhaps, to the prodigies of the lowcountry, will show you that we have got the right kind of article in this part of the world.

Apropos of stumps, my own experience has been that they are far preferable to plants, especially if the latter are very big. Some plants I put out a month later than the stumps are nothing like their size, though they began by having the advantage by a couple of inches or more.—Yours faithfully, T.

[The leaf sent is a very fine specimen indeed: 9¾ inches by 4. We got one 10½ inches long, but that was on virgin soil. All we have ever seen were eclipsed, however, by the foot-long leaf from Mymensing indigenous, grown on Somerset estate, Gampola.—ED.]

MR. ARMSTRONG ON TEA PLUCKING.

23rd August 1884.

DEAR SIR.—With reference to my friend Mr. Christie's remarks on tea plucking at the Maskeliya Association meeting on the 15th instant, I am sorry I differ from him with regard to *fine* plucking. I do not believe in too coarse plucking, which is sacrificing both quantity and quality. But I do believe in "*medium fine*" as against "fine": the former gives us both quantity and (good enough) quality Now with regard to fine plucking, in the cases quoted by Mr. Christie, will he kindly consider the following:—What is the difference in cost of manufactured tea between his fine and his coarser plucking? Has he tried field against field, *in the same season*, as to difference of yield? as the mere fact of his showing us a loss of only 4,000 lb. in fine plucking, if he has not done so, proves nothing. Supposing his garden to be at a high elevation, with a heavy and *constant* rainfall, this season was entirely in its favour; and I think, if such is the case, his yield as against last season, with bushes in good order, as I understand they were, should have given better results in quantity and not less, although finely plucked. Premising this, then, his lose with regard to quantity would have been far greater than he proves it to be. Will his higher average (he certainly should get a higher average price with fine plucking) as against higher cost and loss of yield, to say nothing of the strain on his bushes, compensate him? I think not. With regard to exhaustion of the soil, I do not think there is any difference, as Mr. Christie says, between fine or medium or coarse plucking, but, with regard to exhaustion of the plant, I think there is every difference in favour of medium as against fine. I must not omit also to draw attention to the fact that when 392½ lb. per acre were obtained as quoted, as against 350 fine plucking, coarser plucking was only continued for half the year; had it been continued throughout, I fancy the difference in yield would have been double or 8,000 lb. instead of 4 000 lb, or 432 lb. per acre as against 350 per acre fine plucking. Time will not permit me to dilate on this subject, a most important one to us all, and I trust Mr. Christie's wishes will be complied with and that all who can will give us their experience of the two modes of plucking: fine or medium. Coarse plucking, unless bushes are very young when it must be done, *i.e.*, leaves must be left till they are almost fully developed, is quite out of the question, giving us neither yield nor value.

It is well to bear in mind that the highest averages, pleasant to see, do not necessarily mean highest profits.
—Yours truly, C. SPEARMAN ARMSTRONG.

FINE TEA PICKING.

Maskeliya, 27th Aug. 1884

DEAR SIR,—It would be presumption on my part to attempt to enter upon a "tea" discussion with Mr. Armstrong. I therefore only answer his letter to explain what, apparently, I had not made plain, and to elicit further information upon the subject. The facts and figures quoted in the remarks which I made at our District Planters' Association meeting were supplied by one of our most experienced tea planters, the deductions from these facts were my own. The estate referred to is not in Maskeliya, and Mr. Armstrong was wrong in assuming it to have "a heavy and constant rainfall."

When Mr. Armstrong suggests that the excess of 4,000 lb. in the 1883 yield would have been doubled had the coarse plucking been continued for the whole year, he overlooks my antecedent statement that "the yield *in the beginning* fell behind the previous year's by about 4,000 lb. of tea, *but since then the fields*

have run alike." There is proverbial safety in the happy medium which Mr. Armstrong, and indeed everyone else, approves of, but the question is: What constitutes that medium? My remarks only went towards showing that the adoption of a system of finer plucking on a particular estate had not so far reduced the yield appreciably or injured the trees. I have heard from a tea planter, second to none in the island, that the class of tea which in past years he made, and which then held its own against Indian teas would not do so now, and I would like to have Mr. Armstrong's own experience on that point. In Mr. Armstrong's invaluable contribution to our tea literature he has given us his Rookwood yields from 165 lb. to start with, up to an estimated 700 lb. for last year. Has Mr. Armstrong plucked finer than he used to do; and, if so, has his yield appreciably suffered? —Yours faithfully, THOS. NORTH CHRISTIE.

PLANTING IN COORG.

High Field, Madenad, Coorg, 1st Sept. 1884.

Dear Sir,—There is an old saying that it never rains but it pours, and there is no mistaking the pouring this last week, having gauged 29·45 inches on this estate, bridges and roads washed away, and (as draining is unknown in Coorg) a fearful loss of surface-soil. Anent draining, I believe, it is to be started at last. The new V. A. of Messrs. Matheson & Co.'s estates (a Ceylon planter) has given orders for the thorough draining of a new 60-acre clearing of cinchona. On the Sumpajee Ghaut alone hundreds and hundreds of tons of good soil has been washed down the hills and helped to silt up the bar at Mangalore. "Can't understand why the ghaut won't give crops," says planter No. 1; "Leaf-disease," says No. 2; "Borer," says No. 3; "Climate altering," says No. 4; and so on, totally ignoring the fact that all their soil has been washed away through want of drains.

Cinchona is looking very well in spite of the heavy rains: those lately planted out have not seemed to suffer much. Officinalis and Condaminea have proved a failure, the elevation being too low. They grow very well in the nursery, but when planted out their growth is very slow and spindy. On going round one of the estates in this district, I noticed that in nurseries where the plants had been left 6 × 6 or thereabouts for shade, nearly all above two years old had gone out. I naturally asked the proprietor what he thought was the reason, when he informed me that it was constant watering that killed them. May not the constant rainfall you have in Ceylon be the cause of so many estates losing such large numbers of trees from canker? In Coorg we have a good 3 to 4 months in the year when we get no rain. At this period the cinchonas partly shed their leaves and appear to sleep, but with the first showers at about the end of March they spring into renewed life and vigour.

A friend of mine was showing a Ceylon planter over his five-year old cinchona estate, when he informed him that he had seen whole fields die out in a very short space of time through canker; but it does not appear to do so here: a few die, and some only as far as the roots and then throw up a sucker. The growth is, I believe, inferior to Ceylon, but that may be on account of the period of rest they get in the dry weather. Can you or any of your readers inform me why trees allowed to seed should be inferior in alkaloids to trees that have never been allowed to seed?—Yours faithfully,

SPENCER MARSLAND.

QUERIES AS TO THE EFFECTS OF THE SHAVING PROCESS ON CINCHONA BARK

The Neilgherries, 6th Sept. 1884.

Sir,—Please excuse my troubling you so soon again, and kindly find a corner in your esteemed periodical for the following queries anent cinchona harvesting.

1*st.*—With regard to the theory that the shaving system of harvesting bark ultimately induces a reduction or deterioration in the total amount of alkaloids in the bark, will Mr. Guard of Cherambady and other planters (with whom sufficient time has now elapsed since they commenced the shaving process to prove by results the amount of truth in the above assertion) kindly inform their brother-planters of more limited experience, whether their experience corroborates that theory? Will these gentlemen further oblige by mentioning—

2*ndly.*—What is the average gain in interval of time in renewing and thickness of bark so renewed on trees subjected to the shaving process as compared with the stripping operation? And—

3*rdly.*—Taking for granted the superiority of the shaving process, is that method of harvesting equally advantageous and applicable to cinchonas grown at high elevations (say above 6,000 feet) as to trees grown at the lower elevations of about 3 000 feet?

Some planters recommend shaving for trees at 3,000 feet and stripping for cinchonae at 6,000 feet. What is Dr. Trimen's opinion?—Yours faithfully, NOVICE.

"JÂT."

Dear Sir,—It must not be supposed, from this heading, that I am about to presume to instruct my grandmother, the public, in all the mysteries of "Jât" good and bad, because I freely confess, that, notwithstanding the attention and study which I have *lately* given to the subject, I am still far from a perfect knowledge, and have much still to learn regarding it. I do not know, for instance, if all the tea in China is of the one single kind known here by the name of that country, neither do I know if the preponderanee of this kind on some of the bearing estates in Ceylon materially affects their crops and their prices, and in what degree. The public is often favoured—and, rightly considered, such private information is a favour as it tends to our instruction—with particulars of the yield of this or that garden, and what they average in selling; but we never hear anything about the "jât" of their tea, unless they want to sell their seed or plants, and then it is always the finest "A. H." Now, although I cannot teach, I can at least warn; and my own experience teaches me that a note of warning cannot be sounded too soon. In the present rush to get the land planted up, I am afraid much bad stuff will be put in. For the sake of the country, as well as of individuals, this should be checked. Will some expert, therefore, give us a few lessons how to tell good from bad jât, China from indigenous, China hybrid from Assam hybrid, and other wrinkles, in *all* the stages and ages of tea plants? To give my own experience: last year I had never seen a tea-plant, and yet, anxious to save the season like a good many more, I rushed into planting. The first lot of plants I bought (indirectly led thereto by a "V. A." who suggested to a 'cute gentleman on the Awisawella side of the country that I was an inexperienced "B. F." *—since initials are in fashion in Ceylon—much in want of tea plants in a hurry) I paid R7·50 a thousand for. This season *I am pulling them nearly all up again*, and supplying generally between every plant with a better and faster growing jât. Better plants are now being advertized by an enterprizing native at R1 per thousand! Fortunately, I got alarmed in

* "Blessed Fool."

time and countermanded all further orders for *such* plants and seed. So much for my own experience. Only quite recently a gentleman well up in jât was on his travels, and reported to me that in a certain district he saw thousands of purchased plants *of the rankest China jât* being put in with the most perfect confidence in their immaculate breed.

LEAF-DISEASE, NEW PRODUCTS, &c.

No. V.

THE COCONUT TREE AND ITS USES.

SIR,—The cocoanut tree belongs to the tribe of palms. It is said, and truly so, that of a cocoanut tree a ship can be built and laden too. It grows to the height of 60 or 70 feet, from the root, and the trunk gradually tapers, and almost at its summit it spreads out into what are called branches with beautiful foliage or leaves; these leaves grow on the so-called branches, and each leaf is divided in the centre by a thin woody rib which is called the mid-rib. The leaves are useful both in their fresh and dried states. The dried leaves are, after soaking for a short time in water, separated from the branch and dried and plaited, they form a plaiting of leaves woven into each other and are called cadjans; these cadjans are used for covering houses, fences, and roofs of country vessels. The leaf and branch or leaf-stalk undivided and plaited with one another make a good substitute for tats, and are cool and refreshing when fresh. The trunk of the tree at its lowest part is six or eight feet in circumference; when divided into two, it is used as gutters and in some places as rafters, but is not equal in duration to the palmyra rafters. From the bottom upwards there are concentric rings which mark the place where the old leaves were attached. The flowers are generally enclosed in thick horny-looking but fleshy cases which are called spathes; they are in clusters on each side of a stalk. From the spathe and flower a liquid substance is obtained resembling watery milk which is called toddy. This is sweet and refreshing when fresh, but when exposed or kept too long becomes sour and intoxicating. Spirit called arrack is obtained from the toddy in such large quantities, as to afford a revenue to Government, and an article of trade. Of the sour toddy vinegar is made; from the sweet toddy collected in large quantities boiled and evaporated a sweet substance is obtained which is called jaggery. The fruits grow in clusters; some varieties of them are comparatively large; when tender or fresh plucked, the nut has a green fibrous coating under which are fine fibres of a reddish yellow color which cover the shell. The shell is hard and woody; it encloses the white fleshy kernel and some water. The outer covering of the coconut, although generally cast away, when dried may be used for fuel; the underlying fibres when washed and cleaned and separated are called coir fibres. These fibres are used for a variety of purposes: they are made into coir rope of different thickness and strength; they are made into mats, rugs and brushes, and have been plaited and made into hats and bonnets; they are also used for cushions and mattresses and many other things. The shell can be divided into two and used for ladles, cups and drinking vessels; sometimes only the top piece is sawn off and graven with varieties of designs. The kernel is a white and comparatively soft substance which is found inside the shell; in its early stage it is like jelly and can be easily scooped out and eaten; it is cooling and refreshing. In an advanced stage it is harder and may be scraped; in this stage it is used in making cakes; when boiled with sugar it is called "chuncha" or "chinchareen" in Portuguese. This is put into pancakes and rolled and is called "throothas' When still more hardened and matured it is scraped out, and milk is expressed out of it which is sweet and of a thicker consistency than cow-milk. The milk is used for compositions of curries and forms a nice gravy when boiled together with curry-stuffs, etc. It is largely used for this purpose by the people of India and Ceylon. When boiled and evaporated, a fine clear oil is obtained which is used as hair-oil and is the best for improving or promoting the growth of hair: it makes the hair soft and glossy. The refuse of the scraped coconut makes very good food for poultry. The coconut when allowed to dry to some extent is an article of trade and exportation and is called copperah, and the oilmongers extract large quantities of oil, which is used for lighting purposes. It is extracted by a rude kind of mill called chekku, made of wood and worked by bulls. The refuse after being extraction comes out in large cakes and is called poonac, which is used as food for animals and may also be used as manure for trees.

By way of recapitulation it may be stated that a vessel may be built by layers of rafters both for the ribs and the sides of the hull of the vessel. The interstices or seams may be filled by coir fibres then caulked and painted. The floor of the deck may be laid with rafters and these also caulked and painted. The mast may be made of the well-seasoney trunk of the coconut tree. The rope and hawsers mad be made of the fibres; the sails may also be made of the same. Then the vessel will he from stem to stern made entirely of the coconut tree. It may be laden with the following:—Coconut rafters, coir yarn, mats, rugs, brushes and coconuts. It may also be laden with arrack, jaggery, copperah, coconut oil, poonac and cadjans. So the vessel will be actually built and laden with the coconut tree itself. There are several kinds of coconut: the ordinary "nawasi," of which the fleshy covering of the kernel is tender and may be eaten, is of a sweet taste; the king cocoanut, the outer skin of which is white, is of two kinds, the large and small size; then there is what the Tamils call "suriya kavelle" (sun-faced)—if the stalk-end of the surface of the coconut is cut, it presents a beautiful red appearance; this is supposed to be caused by the face of the sun, but how it is so is not known—the natives use this kind particularly for medicine. Then there is the small hard kind which the natives call "pora tengai," the shell of which is very hard, and they use it for breaking against each other on their New Year's festival, which is about the 12th of April. Then there is the dwarf cocoanut tree which looks very ornamental, and the Maldive is also another kind of cocoanut.

SILEX.

GROWING HOUSE PLANTS IN MOSS.—In some of the Swiss villages nearly all the inhabitants are engaged in watch-making. They work in large rooms, which, being abundantly lighted and well warmed allow the workmen to cultivate plants, that, on account of the uncertainty and rigour of the climate cannot be grown in the open air. The President of one of the local horticultural societies in Switzerland gives in the *Revue Horticole* an account of the great success with which plants are cultivated in moss in these watch factories. One great advantage in the use of moss is the readiness with which plants may be grouped in large vases and boxes. In France a "fertilized moss" is sold, but ordinary moss with occasional application of liquid fertilizers will answer as well. Ordinary sphagnum or peat moss, such as is used by florists in packing, may be employed, but the writer prefers the moss which grows in sheets upon rocks and around the trunks of trees at their base. Wire baskets lined with this moss are used, as are jardiniers of metal, glazed pottery, etc., taking care to provide sufficient drainage. The liquid fertilizer used on these house plants should be without unpleasant odour; weak guano water, solutions of nitrate of soda or sulphate of ammonia may be employed, and very fine flour of bone may be mixed with the moss.—*American Agriculturist.*

TRINIDAD AGRICULTURAL ASSOCIATION.

THE CURING OF COCOA DISCUSSED.

A meeting of the abovenamed Association was held on Monday, 28th ultimo, in the Town Hall, Port-of-Spain. The President (Hon. Léon Agostini) occupied the chair, and there were also present the following members:—Messrs. Eug. Lange, Sr., Chas. A. Fabien, W. S. Tucker, W. F. Kirton, the Hon'ble L. A. A. De Verteuil, the Hon'ble G. T. Fenwick, A. Wuppermann, G. Grant, B. Devenish, C. G. Scheult, Dr. Urich, F. Urich, B. Kenny, E. S. Giuseppi, E. H. Man, L. de Lapeyrouse, S. Henderson, Dr. Murray, J. H. Connell, A. Briggs, J. E. Coryat, René de Verteuil, H. Prestoe, J. S. Wilson, M. Lennon, Jules Maingot, F. Gransault, J. Laing, and John McCarthy, Secretary.

The Chairman proceeded to make some remarks with reference to the Judges in the recent Exhibition, in the course of which he stated that the best thanks of the Society were due to the Judges for the able manner in which they discharged their duties. He stated that special thanks were due to the Judges of the Cocoa Section for their very able and interesting Report. The Chairman further explained that the reason why no Report was sent in by the Judges of the Sugar Section was that the Judges, not being aware that a Report was necessary, kept no notes.

Mr. McCarthy (the Secretary) read the following paper, written by Mr. W. S. Tucker, of Macquerepe, on practical observations made in the Curing of Cocoa Beans:—

My original idea was to explain verbally my experience in cacao-curing, but acting on the advice of certain friends, among whom I may name our Secretary, I was induced to put on paper the following details, which, on account of my defective sight, the Secretary has kindly promised to read.

The tone taken on the whole subject is decided, and I trust the subject-matter will elicit discussion, exposing any faults and suggesting improvements.

As a preface, perhaps I may be allowed to state the circumstances and some of the causes which enabled me to be in a position to describe cacao-curing and drying, as during my long residence in this colony, I have not been known generally as a cacao planter.

A good many years since I became proprietor of two estates in the valley of Cuesa.

On these lands I allowed many persons to make gardens and plant cacao. Some years after a great fire destroyed the whole of the cultivation. Later on, a larger portion was planted in cacao, and after a partial survey in 1877, I was induced from the promising appearance of the district to take over the planted portion. This, in conjunction with other smaller pieces planted in the valley (of which I am now sole proprietor), became an object worthy of special attention and in consequence I left town and became a cacao planter.

Of cacao planting I then knew nothing, and from the isolated position of my property, I had not the opportunity to avail myself of the advice or assistance of any neighbours. When in difficulty I was obliged to fall back upon my own resources.

I now beg to lay before you the experience I have acquired during the past five years.

No doubt that in taking into consideration the manner in which certain difficulties might be overcome, I was induced to have recourse to well-known methods, but so far as I was concerned, they were perfectly new. My first crop was 36 bags. The cacao was gathered, brought into the yard, and, for four or five days, fermented in packing cases; the cacao was subsequently dried on old tarpaulins. This lot was shipped and realized a medium price; complaints were at the same time made as to greenness and dark colour.

I felt satisfied I could get over the colour difficulty, but greenness somewhat puzzled me.

The question occurred to me, how can ripe cacao be considered green?

In the following shipment I overcome the colour difficulty by short fermentation, and this, coupled with a bright sun, produced bright red nibs. This sample was forwarded with another lot very dark on the outside. To my surprise and disgust, on the receipt of the account-sales, I found that the dark variety was valued higher in the Home markets, and that the red variety was pronounced green.

This result prompted me to make another effort, and with the experience which I had already acquired, I determined to produce an article suited to the demand. After years of trials, attended with the loss of much valuable cacao (in one year as much as 70 bags) I found it impossible to depend on the present method of drying, in order to produce uniform qualities. Subsequent experiments with artificial drying proved to me that the desired object might be obtained by this method of drying, provided the cacao was previously fermented in a special and careful manner. With this combination of drying and fermenting, I am of opinion that any quality of cacao can be produced.

I will proceed to lay before you what my experience has been in connection with the matter.

My first trial in fermentation was, as stated, made in cases; this plan I found after a time defective on account of its liability to generate mildew. Subsequently, I had bins made of brick and perforated at the bottom. This method was successful so far as the retarding of the formation of mildew was concerned, but great difficulty attended the necessary cleanliness of the bins.

Even with best attention, it was impossible to retard the formation of a hard concreted mass, which was quickly produced below during the fermentation.

This formation was possibly caused by the current of air passing through the perforated lower part, which was necessary to supply the air essential to healthy fermentation, and the air probably supplied the lower organisms or fungi, which by their development and propagation produced the concreted mass abovementioned. With a view to stopping, or at least retarding this formation, I moved the cacao every two days. This seemed, by mixing the mass, to equalize the fermentation; the resulting cacao was much darker than the ordinary.

I next tried fermentation in air-tight puncheons, and this produced, after 30 days of cold fermentation, a more equal internal result; this fermentation might be better regarded as a slow decomposition.

The chocolate made from the cacao thus fermented was of an exceedingly delicate flavour, highly digestible, with no appearance of oil when prepared. This cacao would not admit of any adulteration.

Cacao fermented in the above manner should be dried immediately, otherwise an unhealthy decomposition takes place.

My next experiment, which I may mention, was a decided success, was to ferment in puncheons three-fourths filled with cacao. These puncheons were made to revolve in a frame, like an ordinary grinding stone, and were uniformly perforated and placed in the open air, in order that the sun and atmospheric influences might have full effect. The puncheons were revolved every morning for fifteen minutes, thus ensuring the thorough mixing of the cacao. Eight days of this treatment gave the following results:—The appearance of the whole mass was a deep rose brown colour, mildew not perceptible. Internally the fermented nibs were more equal in colour and taste. In my opinion this result proved that the method was superior to the others, in so far equalizing the substance and allowing one to stop fermentation at any moment, with a fair degree of certainty as to the uniformity of the resulting product. Observation and experience show that when the fresh cacao is brought in, each nib is enveloped in a white thick viscid pulp.

This pulp is then fruity to smell and pleasant to taste. It subsequently becomes the chief cause of diminishing the quality and value of cacao. Formed with the nibs in the pod it has a most tenacious hold on them, and the only way to remove it is by fermentation. During fermentation, if improperly conducted, it becomes the chief source of rot or mildew. When the cacao is under-fermented, the mildew appears in dark, narrow and broad lines.

When the cacao is highly fermented, the mildew is spread over the surface of the nib, darkening the colour.

The following are my practical observations on fermentation:—

1st day.

The fresh ripe cacao when put into the bin is externally covered with a viscid white pulp, very humid.

Internally—Colour dark purple, hard and gummy in appearance, taste bitter.

2ND DAY.

Externally—Slightly altered to a reddish hue.

Internally—Appearance, alteration in colour, taste bitter, pulp acid.

Ferment—Warm to feel.

3RD DAY.

Externally—Colour more red, pulp fermenting.

Internally—Colour brighter, appearance of the liquor of fermentation, taste bitter with a pleasant acid flavour.

Ferment—The mass heated up to 100 to 110 degrees.

4TH DAY.

Externally—Deeper red, pulp fermented and very acid; patches of white mildew appear on the top and sides of bin.

Internally—Colour brighter, liquor of fermentation increased, producing a dark purple viscid solution, which is perceptible through the whole of the cotyledon.

Taste acid—bitter, with a cacao after-flavour.

Ferment—Heat to its full height, generally 120 degrees.

5TH DAY.

Externally—Colour reddish, pulp less liquid to feel, the mass evolving a pleasant fermenting smell sometimes alcoholic.

Internally—Colour much brighter according to the kind of cacao, some of a lilac colour (the best quality), other portions darker, and a light purple viscid solution developed in full quantity lying free through the whole nib.

Taste—The acid bitter of the first stage now disappears being replaced by a pleasant acid, sweet bitter.

Ferment—Heat up to 120 degrees.

6TH DAY.

Externally—red in colour, mildew increased.

Internally—Nibs generally of a lighter hue, some (the best) turning dark cream colour.

Taste—The same as 5th day.

Ferment—Heat up to 120 degrees, the mass assuming a dryer appearance, giving out a strong odour of fermentation.

7TH DAY.

Externally—Red in colour, mildew more.

Internally—A shade lighter all through.

Taste—The same as 6th day.

Ferment—The same as 6th day.

8TH TO 14TH DAY.

Fermentation goes on modifying both in colour and taste; the cotyledon re-absorbs the liquor of fermentation thereby gradually turning the internal colour to a light brown, forming a most delicate cacao unsuited for the present markets, and not fitted for adulteration.

Externally the highly-fermented nibs are dark in colour.

The cacao, when dried after either of the above days, gives the following indications:—

If dried after the first day the indications are externally bright orange-red, internally a heavy wavy mass, slate purple colour.

Second day—Externally bright red with dark markings of pulp. Internally solid in appearance. Colour, slate-purple.

Third day—Externally bright-red, pulp markings much deeper. Internally the cotyledon split, dark-purple brown in colour.

Fourth day—Externally red with the dark-purple markings more diffused. Internally more open, purple-brown in colour.

Fifth day—Externally red brown, pulp-markings yet more diffused, internally broken, more open-dark colour, aroma perceptible.

Sixth day.—Externally brown-red, pulp diffused all over the surface. Internally dark and light brown, aroma very perceptible.

Seventh and eighth day producing a decided general improvement. Externally of a brown-red or brown colour, showing no pulp marks. Internally the cotyledon is divided from the centre outwards and colored different shades of brown (lightest best). On breaking the nib a pleasant aroma is exuded, this aroma is somewhat increased by longer fermentation.

The alteration taken place between the fermentation and drying is very great, and a description of this change I will now attempt.

The early stages of fermentation bring about a change similar to that which takes place in the germination of malt. The cacao is modified as regards the extreme acrid bitter, as also the colour and density. The fermentation also changes some of the substances into saccharine bodies, and, further, splits the cotyledon. A fact worthy of notice, is that during the fermentation a liquid is formed by chemical attraction and condensation. This liquid I believe to be the true essence and toning matter of the whole bean, and without this, cacao would be merely a dry, tasteless vegetable substance.

Fermentation not only produces all of the above alterations, but changes a hard indigestible matter into one easily digested.

The drying of cacao requires special attention, more especially if the drying is carried on in the usual manner.

Should the weather be changeable much waste and deterioration is caused by the ordinary process of drying. There is no certain dependence in sun-drying, especially in this Island.

My first experiments in the desiccation of cacao were made with tarpaulins spread on the ground an effective and economic plan if properly carried out. After the erection of a cacao house the drying was carried on a wooden floor covered by a moveable roof.

Taking the fermented cacao from the bins, when it is then more or less mildewed, it is subjected to a process of rubbing with the hand or stamping with the feet to destroy the mildewed appearance and diffuse the fermented pulp. This operation does not destroy the fungi but rather incorporates it with the external pulp.

First day's drying.—The cacao after undergoing more or less rubbing to make it of one uniform colour, is placed on the drying floor at a depth of from one to two inches thick; it is then exposed to the sun's rays, and raked and turned over every half-hour. By mid-day there is a well-marked difference in the appearance of the cacao; the nibs are inflated and possess a full red colour, the pulp shows a desiccated appearance and is less adhesive.

Special attention must be paid to inflation in order to produce a good marketable article. Towards the after part of the day, the larger proportion of the nibs are seen to have a small globule of the liquor of fermentation which oozes from the inside; this effect should be avoided if possible, and this effect may be accomplished, by, during the hottest part of the day, heaping the cacao to allow a partial collapse.

A mid-day fermentation is beneficial more especially to an under-fermented cacao, as the latter then undergoes what might be called dry fermentation, which decidedly improves the quality. This operation should only be attempted in sunny weather. By sun-down the cacao will have a dry appearance and feel, most of the nibs being inflated.

Second day's drying.—The appearance of the cacao on the opening of the house was as follows:—The cacao was covered with a frosty-like mildew more or less intense on the humid spots. The greater portion of the inflation had disappeared. The mildew is subsequently rubbed off and the cacao left to dry. The cacao is raked as before, and after some time re-inflates, but not to the same extent as on the first day.

By evening the cacao externally is dry to feel and look, internally it is somewhat humid, the liquor of fermentation having being partially absorbed, thus producing a gummy feel.

Third day's during.—The cacao may have a slight mildew from the moisture which exudes from the nib during the night. This moisture is soon evaporated, and by evening the cacao is dried sufficiently to finish in the shade. A further day's sun is however preferable, as it gives to the husk that peculiar sound so desirable when the cacao is being tested; it further ensures complete desiccation.

Should the weather be showery or what is still more to be feared wet, the drying operations may take from 4 to 12 days to complete—every day after the fourth brings with it a considerable increase of fungi, ending in a black husk externally and possibly rot internally. These can be detected by a slaty-black appearance and disagreeable odour. The different colours on the outside of the nib are due to solar action, in combination with the acid of the pulp and the tannin of the husk: these produce a cacao which is

more or less darkened by an infusion of fungi. Cacao shipped with a slight internal humidity generally improves by dry fermentation during the voyage.

After trying the above-mentioned experiments, and not having obtained any really reliable result, I was induced to make certain experiments with artificial desiccation. These experiments have been carried on for the last three years with more or less success. Some time ago the Cacao Planters' Association imported one of Gibbs' drying machines. In this machine the cacao is caused to revolve round a heated tube. The machine remained for months untried, and to further my experiments I determined to give it a trial. After some difficulty I obtained the machine, and it has materially assisted me in arriving at what I believe to be complete success. The cost attending the experiments with the machine was very great, as it was unsuited in character and form for cacao-drying. I have dried cacao in seven hours, and from the experience gained in the experiments detailed, I have devised a simple machine, which contains every requisite for complete artificial desiccation.

My formula for producing the cacao which was shown at the recent exhibition is as follows:—After taking the cacao from the fermenting bin, it is thoroughly washed in running water to completely remove all fermented and mildewed pulp and other foreign matters. The cacao is then drained for half an hour, placed in the first dessicator for two hours, then removed and placed in the finisher for three or four hours. This produced a cacao perfectly dried and in no respect parched. The result afforded me much gratification and pleasure, and enabled me to conclude that cacao could be dried independent of climatic influences. I further learned that any quality of cacao could be produced with certainty by merely modifying the curing operations.

Before leaving the subject there are a few further remarks which I wish to make. All cacao produced for sale is prepared in an extremely unclean and unsuitable manner, deception is too frequently used (and unfortunately not sufficiently decried in the market) to cover the colour of nibs. Articles such as starch, gum, red-ochre, rancid butter, mud, clay, sour orange and many other undesirable devices are employed. To this artificial desiccation says decidedly:—"It is wrong."

The same energy and attention given to the internal improvement of the nib would give more profit and a better name to the article. Another fact I discovered and which is a highly important one in the production of good cacao, more especially when the estate contains many varieties, is, that to form a superior article it is essential that the trees be past maturity; a better quality and size of fruit is thus ensured.

I have observed cacao from the matured estates of this Island, and I am of opinion that had it been properly treated by artificial desiccation, the article would have been in every respect unsurpassable, ensuring to the manufacturer cacao suited to his requirement.

The paper having been read, Mr. Lange addressed the meeting and, speaking from his experience as a cocoa planter, said that it was certainly a very interesting subject for every one, and that great attention had been paid to the paper just read. He wished, however, to offer Mr. Tucker an opportunity of giving some further explanation. He did not think that Mr. Tucker had arrived at a conclusion, as to what would be the proper test to be employed in the fermentation; of cocoa, that was to say, what was the last fermentation—the turning point. There was first the vinous fermentation, secondly, it underwent what was called the acetic fermentation; and thirdly, there was the germination. It was obvious your cocoa if too much fermented would develop much germination. What the cocoa planter wished to know was the turning point at which to arrive when the acetic fermentation ceased and germination began. After a certain number of days in the curing house some of the beans were taken and split with a penknife, and certain things were observed, by which they guided themselves. Now, as to the degree of heat you would allow, in fermentation Mr. Tucker mentioned 112 degrees.

Mr. Tucker: 120 degrees.

Mr. Lange said that Mr. Tucker had always used 120 in order to have successful fermentation, but that was only one test. He might ask for information also with regard to the drying process; what Mr. Tucker called "rot," he (Mr. Lange) supposed was mildew.

Mr. Tucker said that, externally, it was the rotten pulp, after eight days' fermentation. Then, decomposition takes place internally. That was what he meant by the rot of lengthened fermentation. After being fermented for a certain time internal decomposition takes place and rot was the ending of it.

Mr. Lange said that Mr. Tucker's ordinary process of drying was what was done on all cocoa estates, but with regard to the artificial experiment of Gibbs, he found that Mr. Tucker's description of it was not exactly what it should be. It was to his (Mr. Lange's) recollection, a cylinder into which the cocoa was placed, with a furnace at the other end of the cylinder, and by means of a fan you drove hot air into that cylinder. Some members of the Cocoa Planters' Association subscribed to get out that machine. He mentioned this because Mr. Tucker described it there as a hot air tube, and because he (Mr. Lange) was now preparing an experiment on the principle of the hot air. He would not like to say that the principle had already been experimented upon; but what they wanted was, to determine when the cocoa was sufficiently fermented, and certainly, should the other members follow the example of Mr. Tucker, it would create discussion and advance the proper curing of cocoa by fermentation or by drying.

Mr. Tucker said he was glad that his paper had brought from Mr. Lange his practical and theoretical experience. In reply to Mr. Lange, with regard to the fermentation of cocoa, his (Mr. Tucker's) experience was only practical. After six days, he took all his cocoa beans, and from their colour and their taste, decided whether the fermentation was sufficient or not. On his estate, where he had a variety of cocoa growing, his cocoa came in and he was obliged to accept it as it came. Consequently, he had had to contend with serious loss. In fermenting, he had been accustomed every day to open half a dozen or more beans, and there he saw the different varieties of cocoa and the colour that they presented. The best cocoa lightened much quicker than the harder cocoa. He was not sufficiently acquainted with the names of the different varieties, but could only mention them by description. The good cocoa was sufficiently fermented in from three to four days; that cocoa lightened internally. On the second day it was considerably lighter; on the first day it was of a dark pink or purple colour; next day it was of a different colour; the third day it became of a pure light colour. He was speaking now of what he considered the first class cocoa. The fourth day it was almost cream colour; if it was not cream colour throughout, the internal portion was cream colour. From that he took it to be sufficiently fermented. Now, in the interior of the bean there was a peculiar kind of dark purple liquid; this, after the first, second, and third day, was profuse throughout the whole bean, and if this liquor was squeezed from the nib, the result would be dry vegetable matter which was comparatively tasteless; it had a slight flavour of cocoa, but nothing more. This was the reason why he called attention here to that matter, which he thought, was the matter to which the whole of the aroma and value of the bean and the food depended. The good cocoa fermented up to the third day contained this matter very profusely. As far as his experience went, if you wanted to produce a first class cocoa, you stopped the first day and allowed the solution to be absorbed while the cocoa was drying, not during fermentation. In the other cocoa it was of a waxy appearance, and it was almost impossible to give that colour; the beans altered in colour considerably but never to the same extent.

Mr. Lange: When does this happen—on the first, second, or third day? Then what course of fermentation had your cocoa—was it during the vinous fermentation.

Mr. Tucker: I should imagine it is in the alcoholic fermentation. Mr. Tucker went on to say that he was not capable of explaining the chemical process of fermentation. He thought that all cocoas could with a proper amount of fermentation be made good—that all could be made a good merchantable article by observation and practice. But, he said he had been obliged to ferment with a mixture of all varieties of cocoa. He thought eight days was the time required for

fermentation. With regard to the machine that he had made, Mr. Lange was in error. The heat generated in the furnace passed through a fan, and was there fanned into a tube about from eight to ten inches in diameter running through a wooden cylinder. This tube was inside of the cylinder. This cylinder had pieces of tin put in it to guide the cocoa, so as to form a kind of worm round the tube, and the cocoa when put in wound round the tube and fell out on the other side. That was the machine that he got from Mr. Gibbs, but he found it was of no use on account of the pulp that was on the cocoa. After using it once or twice, as soon as the matter on the surface of the cocoa became adhesive, it remained there and adhered to the cylinder, it became hardened by the heat, and concreted into a concrete mass which kept the cocoa from passing. Large lumps of this concrete burnt to cinder. The glutinous matter on the outside of the nibs adhered to the side and would not allow the cocoa to pass. That was the Gibbs machine.

Mr. Lange: But you have altered it.

Mr. Tucker said he had altered it (the Gibbs' machine) by making a different machine altogether. There was not only this that he had overcome, but he also found that the cocoa would not dry properly, so as to be a properly inflated bean; it must not only pass through, but must be kept continually in a hot place; it must be retained; the moment you took it out and condensation took place, as soon as it cooled, the bean collapsed—it was impossible to replace that fine round bean that you could make of it. Consequently it required to remain in this hot air a sufficient length of time, or else it became inflated like a bladder and the outside would dry and break. Mr. Gibbs in his recommendation sent along with the machine stated that the cocoa should be taken out and cooled. It was not the thing at all. It should be so regulated that the machine could be constantly kept in motion at a certain temperature, and there the cocoa should remain until desiccation took place in the interior, or throughout the whole of the bean, so that there was, if anything, less humidity in the centre than externally. In his process he could not do what he called the "first desiccation." The cocoa remained there for two hours; it was then taken out of that desiccator and placed in one of lower temperature to be totally dried. There, so far as his experience went, it remained for about three hours. After that time you took the cocoa out and put it down on the floor and allowed it to cool. That inflation was maintained because the inside of the bean was already dried, or very nearly dried, and there it remained fixed, and the cocoa then cooled and the moment it was cool you put it back in the cylinder.

Mr. Lange: And what is the shape of the beans?

Mr. Tucker: Somewhat like a pigeon's egg, more or less inflated, and as I have said when gathered from mature, large, and old trees on the estate, these beans have formed magnificently.

Mr. Lange: You have not told us about the first desiccator, and the form of the cocoa.

Mr. Tucker said that cocoa required a particular form to overcome many difficulties. Cocoa, in drying, appeared to be like no other substance. The temperature in the first desiccator would be from three to four hundred degrees. Gibbs' machine was one hundred and sixty degrees—the highest he could possibly get—the cocoa went through and came out on the other side, just warm; it was brought back, put through again, and came out on the other side just as warm, and he (Mr. Tucker) found that every time it passed through, the inflation caused by fermentation was lost in the drying.

Mr. Lange: But how do you get rid of the pulp?

Mr. Tucker said the beans were thoroughly washed, but for all that still a great deal remained.

The President asked whether Mr. Tucker ever shipped the cocoa, and what was the market price?

Mr. Tucker said he shipped his cocoa, and with all his experiments there had been a difference of one shilling or one and six-pence; and when he had made excellent cocoa, two shillings. When he made very bad cocoa he generally got two shillings less than the normal price. There was no doubt that cocoa so prepared went into a channel, and it showed that the buyers wanted us to send cocoa of that value. He had never shipped cocoa perfectly dried; he had only sent that which was dried by Gibbs' machine, but he had sent a very excellent sample done by Gibbs' machine. He was now taking drawings of the models and he intended to take them to England by the mail steamer on the 7th of August for the express purpose of carrying out his designs. The only person in Trinidad who had seen his machine was Mr. McCarthy, and it was of a peculiar formation to overcome all difficulties; but it could be seen at any time. It could be made to dry within half a bag.

Mr. Wilson asked whether the cocoa beans lost the form (spoken of) after coming out of the first machine, and was it only the skin of the cocoa or the germinating part.

Mr. Tucker: The whole of it.

Mr. Wilson: It actually shrinks?

Mr. Tucker: The collapse takes place from inside of the bean.

Mr. Wilson: There is a hollow?

The Secretary said that the machine of Gibbs' never dried coffee. It was devised on his suggestion. The Cocoa Planters' Association advised him to write to Mr. Gibbs, who was largely interested in the drying of hay, tea, etc. The result was that this machine was brought out, and it was pronounced a decided failure. But it was not a coffee-drying machine.

Mr. Wilson: Mr. Tucker says that beans are subjected to three or four hundred degrees of heat.

Mr. Tucker: It requires the bean, the moment it goes into the desiccator, to be at once heated through. If you just heat the outside of it, when it gets a horny skin it is impossible to re-inflate it.

Mr. Wilson: But would not three or four hundred degrees of heat at once produce that effect?

Mr. Tucker said it was impossible to imagine the degree of heat that green cocoa would take. He took some of the cocoa and put it under five hundred degrees of heat and kept it for half an hour, and when he got it out it was still humid.

Mr. Wilson: But there was no evaporation.

Mr. Tucker: Oh, there was.

Mr. Wilson: There was no current of air through it.

Mr. Tucker: No, except that there was evaporation. It is impossible to parch green cocoa.

Mr. Lange: You gave 324 degrees of what?

Mr. Tucker: Degrees Fahrenheit—three to four hundred.

The President: And how did you get it?

Mr. Tucker: By burning wood.

After a general conversation around the table,

Dr. de Verteuil said that what he had heard stated could confirm what Mr. Tucker said as to the drying of the best cocoa. On the Main, on some estates, they had what they called "creole" cocoa and "forastero" cocoa. They had to be careful in picking them separately, because the beans of the creole cocoa were not so thick as the other, so that from three to four days' fermentation was quite sufficient, because, while the other was thicker, it was also admitted to be more juicy and required more time—from five to eight days, according to the weather, and when the weather was wet it would not ferment properly. This showed really that the quantity of pulp which was round the cocoa had to be taken into consideration when you fermented your cocoa or when you put it to dry. So far, if it were possible to put separately the best sort of cocoa from the other sort, it would be very much better, but in this colony we could not do it. It was clear that the process of fermentation with the best sort of cocoa would take six days; then to dry it you required much less time. Mr. Tucker deserved the thanks of the cocoa planters on account of the strong interest he had taken not only in making experiments but in observing closely how the fermentation went on in the cocoa beans. If some other cocoa planters could do the same thing he was satisfied that before long the aggregate experiments of different cocoa planters would lead them to prepare to a certainty cocoa of the best quality. (Applause.)

Mr. Lange moved a vote of thanks to Mr. Tucker, and expressed a hope that before long his experiments would meet with full success.

Mr. Fabien, in seconding the motion, said he hoped that Mr. Tucker would go home as soon as possible and bring out the machine without delay.

The motion was unanimously carried.

Mr. Tucker next spoke of mildew. He looked to the cocoa planters of this island to try experiments so as to

show us how to dispel it or destroy it. It was all that was bad in cocoa, and was the cause of cocoa not being the wholesome good article that it should be. If that cocoa was to undergo in the docks the same supervision as wheat and other cereals, hundreds of bags would be condemned and burnt; but some how or other it passed and was thrown into the English market to rot. He thought it was our duty to see if we could overcome that. He could not say much about it, except that to him it had been a great source of trouble.

Mr. Lange argued that the existence of mildew was no cause for alarm. When they came to inquire they came to the conclusion that mildew was nothing but a sort of fungus. He was sorry to hear an opinion of that sort from a member of the Society, it being possible that advantage might be taken of it to bring down the price of cocoa. It was to be observed that you sent the very best cocoa to the chocolate manufacturer, and after he had manufactured that cocoa into chocolate he exported it —some of it came here with yellow or blue paper round it; next to that was silver paper, and when divested of all that, you would still find traces of mildew on that chocolate. Therefore he said there was not another substance that got mildewed quicker than cocoa, on account of its fatty matter. It was the same with cheese, it soon became mildewed, but who would say that the cheese was unwholesome? On the contrary, people rather relished it. They must not run away with the idea that cocoa was unwholesome, and he assured them that to do so would make a very great difference in the account sales. He must say he did not agree with Mr. Tucker.

Mr. Tucker said that was prefectly true, but Mr. Lange had forgotten that cocoa was in very great demand. The manufacturers actually battled with one another as to who would get it, and consequently they were obliged to take what they could get. They would williugly offer us more, but we were so conservative in our ideas that we would not be altered and were obliged to give them in great quantities an abominable rotten substance.

Mr. Fabien said that in the fermentation of cocoa, after four or five days, mildew did not set in inside. After five days, if bad weather set in there might be a little mildew on the shell; but they all knew that chocolate was not made from the shell. The shells were removed, and only the interior was used. So that he did not exactly see in what way the fungi, if they were indigestible, would affect the fermentation of cocoa.

The President: You are mistaken there. If you ship 10,000 bags, every single bag is sampled, and if it is mildewed it will cause a reduction in the price.

Mr. Tucker: If wheat and other cereals are found to be what is called "smutty," they are condemned and burnt.

Mr. Lange; That is very different. Speaking of cereals, if you take rye, naturally it is condemned, because it contains a great quantity of ergot, and it will follow very likely that the mildew on that will be poisonous.

The Society then rose.—*Port-of-Spain Gazette.*

INDIA:—CROP AND WEATHER REPORT.

For the Week ending the 10th September 1884.

General Remarks.—The rainfall continues insufficient over the Madras Presidency (the Malahar Coast excepted), and the crops in the districts bordering on Mysore and in Madura and Coimbatore are in a very backward condition. In the eastern portion of Mysore the state of the crops is reported to be critical, though prospects have slightly improved in the province. Pasture is scarce in Bellary and Coimbatore and parts of Mysore. Rain is also wanted in the Deccan and Southern Mahratta country, while in Shikarpur and Ahmedabad the crops have been damaged by excessive wet. In two districts the want of fodder is much felt. Throughout Hyderabad, Berar, Central India and Rajputana the prospects are favourable, though in some localities a break in the rains would be beneficial. The same remark applies to the Punjab and the North-West Provinces and Oudh. In the Central Provinces there has been heavy rain during the week causing floods and much damage to standing crops, especially in Seoni. Prospects have somewhat improved in Bengal with recent general rain, but more is much needed in Behar and Orissa; and the transplanting of rice is retarded. The tea plants in Cachar are reported to have been attacked by the tea bug and red spider, and floods have done some injury to rice; otherwise prospects are favourable in Assam. In Burma the crop prospects are also favourable.

The latest report of the Meteorological Department (dated 11th instant) shows that the rainfall is confined to the North-West Himalaya, Darjeeling, Lower and Western Bengal, the Central Provinces, and the west coast of the peninsula.

Harvesting of paddy, cholum, rabi, and other crops are in progress in Madras, and the kharif harvest has commenced in Northern India, where the land is also being prepared for the rabi. Weeding is much impeded in the Central Provinces by excessive rain. The aus rice harvest is not yet completed in Bengal, and the transplanting of seedlings for the next crop cannot be carried out in several districts till more rain falls.

Small-pox and cholera are present in most Provinces, but the latter is prevalent only in Akyab, Patna, Ahmedabad, and parts of Madras. The usual autumnal fever is reported from Assam, Bengal, and the North-West.

Prices are falling in the Punjab and Nort-West Provinces, while in Bengal they are fluctuating.

Madras.—General prospects fair, except in Ceded Districts, parts of Madura and Coimbatore, where rain is still deficient.

British Burma.—Except for cholera in Akyab and to some extent in Prome, public health good; health of cattle also good. Crop prospects favourable.

Assam.—Weather cool. Transplantiug of sali dhan finished and tea doing well. District heathy.

Mysore and Coorg.—Crops progressing in parts owing to the recent rain but in other places prospects have not improved.—*Pioneer.*

Poett's Planting Scheme in the Northern Territory.—We heard from an Adelaide geotleman who had been a shareholder and director of the Company got up to cultivate "Poett's Land," that coffee and cinchona nurseries were quite successful, but that the capital of £100,000 estimated as necessary to clear and cultivate could not be obtained. We are now sorry to see the following paragraph in the *South Australian Register*:—In my opinion the best planting venture in the Territory, Poett's coffee and cinchona plantation, is on its last legs, Mr. Poett having received word that no more supplies are to be forthcoming. He is at present in Palmerston trying to make arrangements for liquidation, and if possible for carrying on the concern.

Cacao Cultivation.—The publication of Dr. Trimen's report on the enemies of the cacao plant, wind, shallow soil, drought, but especially *Helopeltis*, is followed by the publication in our columns of what promises to be a very valuable treatise on the cultivation of the plant. It has now been proved that cacao is far more delicate and difficult to cultivate than either coffee (before the advent of *Hemileia*) or tea. It is not in all soils or in every climate that the South American plant will flourish. It requires good, deep, rather stiff soil; shelter from wind, and in some cases even a certain amount of shade seems necessary. In any case, shelter trees which will generally yield a certain amount of shade seem indispensable. If, as is supposed, *Helopeltis Antonii* is not indigenous, we fear it has been introduced with the seeds of this valuable but somewhat precarious plant. The great ultimate success of cacao can alone atone for such an introduction, and, meantime we can only hope that the catch-and-kill process may be more successful in the case of "the mosquito blight" than ever was the case in regard to the "May bugs" and their grubs. What we have most to fear is the extension of the sucking operations of the nail-crowned bug from the cacao plants to our tea; but we trust no such calamity is in store for us, or that, if the turn of tea must come, the visitations may be mild and unfrequent.

MARKET RATES FOR OLD AND NEW PRODUCTS.

(From Lewis & Peat's London Price Current, August 28th, 1884.)

FROM MALABAR COAST, COCHIN, CEYLON, MADRAS, &c.	QUALITY.	QUOTATIONS.

TEA CULTURE IN ASSAM: STATISTICS.

We recently published an abstract from the *Englishman* of the figures given in the Report of the Chief Commissioner of Assam on tea acreage and tea yield in 1883 in the two great valleys into which Assam is divided, the Brahmaputra and the Surma. The report of the Chief Commissioner is founded on those of his Deputies, and there are constant questionings of the correctness of the statistics, especially for yield per acre, which are believed in many cases to be greatly exaggerated. There are estates, no doubt, which yield 400, 500, or even 600 lb. per acre, but these are few and far between, and for a general average 300 lb. per acre is rather over than under the mark. Mr. Elliott, in noticing the figures for land abandoned or taken up in the year, the result of which appears to be 45,563 acres increase of area, remarks :—

Under the head of "taken up for tea" is included all land which is reported by the Deputy Commissioners to have been taken up during the year in new tea grants, or in extension of old tea grants; but all of the new land taken up is not intended to be, and could not be, put under tea; much of it may be wanted for fuel, grazing, lines, &c. :—

The largest addition is made in the case of Sylhet, the district which, lying below the Khasia Hills on which Cherrapunji is situated, no less than 37,448 of increase being shown, but a note states :—

This total is the actual difference between the total area taken up in tea grants on the 31st December 1882, as shown in the report for 1882, and the total area shown in the present report for 1883. About 30,000 acres of this increase is due to new gardens in the Balisira Hills, but the figure is only approximate.

As will be hereafter seen, the effects of floods are weaning the Indian planters from their preference for low-lying lands. Of course in 27° north the climate of lofty hills would be severe, apart from the nature of the soil. Here in Ceylon, within 7° of the equator, our climate is genial up to a high altitude, and the very stiffness of our soil is in favour of hill estates. There are elements of confusion in Assam which do not exist in Ceylon. For instance, it is stated by the Commissioner :—

The area of a Government grant made to a tea-planter can be accurately recorded in the register, but the additions which a tea-planter may make to his estate by private purchase or by lease only become known to the district officers if application be made for registration of the transfer, or if the added land be included by the tea-planter in his return of the total land in his possession taken up for tea. On the occasion of a recent inspection of the revenue registers in the office of Deputy Commissioner of Sylhet, the Chief Commissioner found that many planters have taken leases of land from owners of permanent estates, and have not separated their interests, so that their gardens are liable to be sold if the owner of the estate allows the land revenue to fall into arrear. The Deputy Commissioner has been instructed to invite the attention of planters in such cases to the advisability of their registering separate accounts in the Collectorate.

The most considerable extensions of tea cultivation in the Province during the last two years have taken place in the Sylhet district. Nineteen new gardens have been opened in 1883 in the Balisira Hills on land which a Company agreed to take on lease from the Maharaja of Hill Tipperah; but it has since been decided that the Maharaja has no rights in the land and the Company will be required to take a lease from the Government.

Sylhet for 1883, as for 1882, holds the fourth place in the Province as a tea-producing district, and the recent large extensions in the district promise at no distant date to place its total outturn not far short of that of the three districts first in order, *viz.*, Cachar, Sibsagar, and Lakhimpur.

The following extract on the subject of land available for tea-cultivation in Goalpara is taken from the report of the Deputy Commissioner of that district:—

"There is ample land in the Eastern Duars fit for tea, and I have lost no opportunity of bringing this matter to the notice of planters and others interested in gardens. With good land, an ample supply of free labor, good water carriage, good land communication between the Eastern Duars and Dubri or Goalpara (and we have all these), the waste lands in the Eastern Duars must sooner or later be taken up for gardens."

The unwillingness of the Lakhimpur planters to furnish returns is suspicious of diminished yield. Of 202 estates in this district, returns had been sent in for only 101. Allowing for inaccuracies, the land held by Assam planters under various tenures (freehold in very few cases) is well on the round million of acres the figures for 1883 being 923,664 against 587,409 in 1878. In that year the acreage under tea was shown at 109,577 mature plants and 38,263 immature, or 147 840 in all. In 1883 the area under mature plants had risen to 161,707 while that under immature plants had gone down to 27,746, the approximate total under tea at all stages being thus 189,453 acres The reserve is, therefore, no less than 734,211 acres!

Of the acreage under the tea plant, 111,439 are in the Brahmaputra valley and 78 014 in the Surma valley, the chief increase being in the latter in the case of the Sylhet district The planters of Lakhimpur had sent not only imperfect but most misleading returns, representing the yield per acre at 385 lb., when really, from the nature of the season, the returns must have been below those of 1882 when the average obtained was 184 lb.! Men who can descend to such dishonesty ought to be reprobated, especially by their own fraternity. The percentages of increased yield shown were :—

Cachar	...	1·49
Sylhet	...	10·39
Goalpara	...	5·43
Darrang	...	4·06
Nowgong	...	13·83
Sibsagar	..	10·62
Lakhimpur	...	51·76

on which it is remarked :—

The Chief Commissioner has little faith in the statistics of larger outturn submitted from Nowgong and Sibsagar he rejects the increase reported in Lakhimpur as altogether incredible.

It is added :—

Export of tea and export and import of tea-seed, as shown in the trade returns.—The export of tea from the province during 1883, as shown in the trade returns is given below :—

	Maunds.	lb
For the Brahmaputra Valley...	3,37,717	or 27,789,284
„ Surma Valley	1,96,954	or 16,206,500

These figures go to support the totals given by the tea Association.

The tea-seed was exported and imported as follows:—

	Imports. Mds.	Exports. Mds.
For the Brahamaputra Valley...	45	6,693
„ Surma Valley ...	5,227	108

It would thus appear that, of the 6,693 maunds of tea seed exported from the Brahmaputra valley, no less than 5,227 maunds went to Sylhet and other districts in the Surma Valley, leaving a balance of 1,466 maunds for Ceylon and other remote places. What follows is worth noting:—

The Deputy Commissioner of Cachar writes as follows on the subject of tea-seed :—

"The supply of tea-seed from Manipur is small and variable. The extensions in Sylhet and Cachar have caused an un on good seed. It no longer pays to plant China tea; what is wanted are high class, free-yielding plants—

indigenous preferred. The consequence is that a number of gardens are now being planted with a view to produce seed. Very shortly the supply will be considerable, and prices will fall. This will enable all gardens eventually to procure the very best seed. At present the price is as big has R200 per maund. Ceylon and Java get nothing but the best seed. During the year one maund of best indigenous tea-seed was sent from this district to New Caledonia, under the orders of the local Government.

Manipur or Munnipore is famous for its fine type of indigenous plant. It was from a plant grown on Somerset estate, Dolosbage, from seed received from this district that the famous leaf was plucked and sent to us, measuring exactly 1 foot in length—the largest we ever saw or heard of. The Deputy Commissioner of Cachar, after showing that the average yield of that district is a little over 3 maunds, 258 lb. writes :—

This is very low, indeed, and unless the outturn can be increased, many gardens will have to close before long. Kamrup, as usual, shows the lower yield, with 179 lb. only per acre of cultivated plants; the reason is that many of the gardens of this district are worked by natives who prefer cheap management and an inferior outturn.

In regard to cost of cultivation and production, the estimates vary exceedingly, as our readers will see from the following extract :—

Cost of cultivation and production.—The district reports contain the following remarks on the subject :—

The Deputy Commissioner of Cachar writes :—"The cost per acre of a well-managed garden is estimated by experienced planters at R80, and the cost of manufacture at four annas per pound: of course, this cost of manufacture includes the cost of cultivation and all other local expenditure; the Calcutta and the London charges are not included. Hitherto, the cost of cultivation and manufacture had been estimated at a much higher figure. Some reduction has undoubtedly been effected by the strict economy observed now-a-days in the management of gardens. If every pound of tea produced in the district cost four annas to manufacture, there was an expenditure of R3,150,036 on the industry during the year under report. This would give an average yearly expenditure of R17,500 per garden, or R1,460 per mensem on each garden. The average expenditure is undoubtedly higher than this. The treasury accounts show that just over 24 lakhs of supply bills were cashed for gardens. It would be more correct, I consider, to take six annas per lb. as the local cost of manufacture per pound of tea. In a garden yielding 4 maunds per acre, the cost would be R80 per acre of cultivation, and R10 per maund for actual manufacture, making a total cost of R120 per acre, *i. e.*, 6 annas per pound of tea."

The Deputy Commissioner of Sylhet writes :—"The cost of cultivation, as reported, may be anything up to a maximum of R190 per acre. The average cost of this and the preceding years is compared below :—

			R.	A.	P.
1880	...	...	71	8	0
1881	...	..	49	0	0
1882	...	...	59	11	0
1883	...	...	53	14	2

The cost of manufacture may be set down as about 5 annas."

The Deputy Commissioner of Goalpara says :—"I think that in round numbers R50 per acre would cover the cost of cultivation and 2½ to 3 annas per lb. the cost of manufacture."

In Kamrup "the cost of cultivation during the year ranged from R30 to R120 per acre. The cost of manufacture varied from 5 to 9 annas per lb."

The Deputy Commissioner of Darrang says :—"I should estimate that the average cost per pound throughout the district would be between 4 and 5 annas."

In Nowgong "the cost of cultivation is said to be about R70 per acre, and of manufacture about 7 annas per pound. These figures were returned last year. The cost of cultivation is perhaps, correct, but I think the cost of manufacture is put down at too high a figure; I think 4 to 5 annas would be a fair rate."

The Deputy Commissioner of Lakhimpur writes as follows :—"The cost of cultivation and manufacture has been variously returned by the planters from R40 to R66-5-8 an acre, and from 4 annas to 8 annas a pound. I think 5 annas to 6 annas per pound would fairly represent the cost of manufacture in the district."

In summing up the character of the year, *hail* is referred to as having damaged the young flushes in March in Cachar, while the floods of May upset all previous calculations.

The "blight" spoken in the following extract was undoubtedly *Helopeltis Antonii* :—

The rice market ruled high throughout the year, the crop having been a partial failure especially lower down, from whence much of the district food-supplies are drawn. All this tended to interfere seriously with the tea industry. The Assam bug blight, and other pests were less numerous and destructive than in other years. The damage done by red spider, &c., is as nothing compared to that wrought by 'blight,' and it is a matter for great satisfaction that the year under review was particularly free from this calamity. The floods possibly destroyed the germs by drowning the plants whereon they grow. The rage for planting low swampy lands which has prevailed for the past two or three years was greatly checked by the unprecedented floods of May, which overflooded all such lands and did much damage to tea."

Sylhet suffered much from heavy rains and floods. What is said of the capricious habits of "blight" with reference to Darrang is worthy of much attention: all pests seem to be intermittent, except the coffee leaf fungus :—

In Darrang, "owing to the prolonged drought at the beginning of the year, the season was a very late one. Mosquitoe blight, which was confined in the previous years to the gardens east of the Boreli, made its appearance on some of the gardens to the west of this river, while it was also bad on some to the east. It, however, proved itself, as usual, very capricious in its course, visiting one or two neighbouring gardens, and then appearing. In others some distance off, passing over those between.

Several gardens in North Lakhimpur suffered from mosquito blight. We now come to a very valuable table of the rainfall of the principal tea-growing districts of Assam. We give the figures for 1883 and the averages for the previous five years :—

A statement of rainfall at the head-quarters stations of the tea districts for the last six years is given below :—

	1883.	Average for the previous 5 years.
Silchar ...	160·44	118·51
Sylhet ...	148·36	167·32
Dhubri	70 37	107·39
Gauhati ...	59·26	70·69
Tezpur ...	72·24	86·08
Nowgong ...	72·32	77·68
Sibsagar ...	85·44	93·33
Dibrugarh ...	104·26	114·78

It will thus be seen that in the very home of the tea plant, the average rainfall varies in an ascending scale, thus :—

70·69	inches.
77·68	,,
86·08	,,
93·33	,,
107·39	,,
114·78	,,
118·51	,,
167·32	,,

It will be observed that four of the districts receive less than 100 inches per annum and that four receive over that amount. The first four represent fairly various districts in Uva, while the other four correspond closely with the rainfall of the young districts, Dimbula, Dikoya and Maskeliya; but the case of Darjiling, with a rainfall ranging up to 250 inches, shews that excellent tea can be grown with a much higher rainfall pre-

vailing than exists in Assam. We in Ceylon have rainfall over large districts, such as prevails in Assam and Cachar; we have hail merely as an occasional curiosity; our climate is far more favourable for human life and more genial for plant life than Assam; our soil, if not equal to that deposited by the Brahmaputra, is a very good tea soil; we are favourably situated as regards labour, means of communication and proximity to shipping ports; so that altogether the advantages seem to be largely in our favor.—Prices realized for Assam teas are not generally recognized as satisfactory, the fall being from 2s per lb. a few years ago to 1s now. The Deputy Commissioner of Cachar wrote:—

Many concerns are already working at a loss, while many more are dangerously near the line that divides profit from loss, so that any further fall in the market would be a serious matter for most gardens.

The Deputy-Commissioner of Lakhimpur says:—"The prices in the Calcutta market ranged from 5 annas to R1 per pound, and were somewhat better than in the previous year. The larger concerns are believed to have paid fairly well during the year. With the general fall of prices (in recent years) there has been manifested a marked tendency in this district to reduce expenses of working by amalgating gardens lying close together to some extent: also native agency is being substituted for the more expensive European management.

Markets.—The Tea Association report that there was a falling off in shipments to Australia and America of nearly 2½ million pounds of Indian tea in 1883, as compared with 1882. The loss of these markets to the Indian crop is very much to be regretted. Mr. A. C. Campbell, the Deputy-Commissioner of Kamrup, writes as follows on the subject of the possibility of Assam planters finding a market for brick in Thibet: "The prunings and the younger stalks, which are thrown away by planters or used as manure, might be sold at highly remunerative rates for export to Thibet, if manufactured into brick tea. I purchased at Dewangiri this year for R4 a packet* of brick tea weighing about 4 lb., and I ascertained that the amount which I paid was the usual selling price of the article among the Bhutias and others. The packet consisted exclusively of old pruned leaves compressed in a mould with about 20 per cent. of young stalk. It was wrapped in three folds of thick paper evidently manufactured in China. I was informed that a very large trade is carried on in the article, and, although the Bhutias and Thibetian traders would not be able to pay cash for it to Assam planters, it might be bartered for blankets, lac-dye, and other commodities which could be easily converted into money."

Profits of the Industry.—The list published by the Registrar of Joint Stock Companies at Calcutta, relating to the year ending the 31st March 1884, contains the names of 53 Tea Companies known to hold estates in this province. Against two of these, no paid-up capital is shown and no accounts of profit or loss are given. The remaining 51 represent a paid-up capital of R1,67,32,467; 38 of these have struck their balance sheets of profits and loss up to the 31st December 1883; and one Company up to 30th November 1883. Of the 39 Companies which show a balance sheet-sheet of profit and loss in 1883 26 Companies show profits amounting to R5,21,692,; eleven Companies show losses amounting altogether to R2,13,72,; to show no profit or loss. The net returns upon the capital employed during the year 1883 by the 39 Companies which struck balance-sheets for the year were, therefore, R3,07,971, or 2·2 per cent. on their capital of R1,35,87,695; the 26 Companies which made a profit obtained a return of 4·9 per cent, on a capital of R1,05,53,905; while the eleven losing concerns lost at the rate of 7 per cent. on their capital of R30,34,600.

As the Brahmaputra and Surma Valleys have been so frequently mentioned, our readers may wish to know which tea districts are included in each. We therefore give the details:—

ASSAM OR BRAHMAPUTRA VALLEY:—

Goalpara; Kamrup; Darrang; Nowgong; Sibsagar; Lakhimpur.

SURMA VALLEY:—

Cachar; Sylhet; Khasia and Jaintia Hills.

The day is coming when Ceylon, utterly unthought of as a source of growth and supply at the time cultivation in Assam was taken up really in earnest some thirty years ago, will rank with the best and most productive tea-growing countries of the world, leaving China far behind as to quality and running Assam a close race as to quantity.

* The Chief Commissioner sent this packet of brick tea to the Indian Tea Association, and suggested that the Association might do something towards making Mr. Campbell's suggestions known.

JACKSON'S PATENT TEA-DRYING MACHINE,

which we noticed recently, is thus described in the *Indigo and Tea Planters' Gazette*:—

In the *Indigo and Tea Planters' Gazette* of 13th May last I described this, the newest and best tea-drier. I also predicted that "if successful, which it can hardly fail to be, it will be by far the best tea-drier in the market." I am happy to say that the machine has been tried, is working, and has amply fulfilled my expectations.

The first machine has been erected in the Cinnamara Tea Garden of the Jorhat Tea Company, and began to work on the 16th July last. It has been working steadily ever since, has been seen by many of the planters of that and other districts, and has been much thought of by everyone who has seen it. Last, but not least, it is giving every satisfaction to the hard working and energetic Superintendent of the Jorhat Tea Company, and as Mr. Huttman is an experienced and successful planter and *one* of the *advanced* school of planters, his opinion is of no small value.

As I described the machine before, I will briefly recapitulate the description. The tea is fed into the machine from a hopper, which, by a peculiar shaking motion communicated to it from the driving shaft of the machine, distributes the tea evenly and automatically over the travelling web which it falls upon on its first entrance to the machine. This hopper is sufficiently large to contain a fill of the Excelsior or any other large rolling-machine. The *fill*—two to two-and-half maunds—may be emptied into the hopper and left there, the man or boys who bring the fermented leaf being employed, while it is passing through the machine, in removing the dried tea. Let me here direct the reader's attention to the great saving in labor which the invention of the automatic feed effects as compared with any other tea-drier. As for *choolas*, they should now be considered things of the past. *One man and two stout boys are able to attend to this machine*, which will turn out *at least* 2¾ maunds of *pukka* tea per hour.* It has actually turned out more than this.

When the tea leaves the hopper it falls upon a travelling perforated web. This web consists of a number of long narrow strips of iron, the iron being coated with lead to prevent injury to the leaf. These strips are carried along through the machine by endless chains at each side of the drying chamber. They overlap each other so that no *kutcha* tea can fall through. At the end of their travel in each direction, the chains, carrying these strips, pass over wheels which give them their motion. The perforated strips are hinged into the links which form the endless chains, so that at the end of the travel in one direction the strips tilt over suddenly, thus not only discharging the tea on to the next web, but by the jerk of the sudden tumble-over dislodging any particles of tea which might have a tendency to adhere to the web. They also thus hang down perpendicularly from the carrying chains while on the return journey, thus allowing the hot air to pass through them. The tea passes along the second web in the reverse direction to the first, and so on back and forward over three more webs, until it is finally discharged dry at the outlet.

As I described the heating apparatus before, it will be unnecessary to go over it again. Suffice it to say that the machine is equal to any in economy of fuel, and will be still further improved in this respect. As it stands, how-

* Or 220 lb.—ED.

ever, the idea has been so well thought out by the inventor that, except in a few trifling minor details, the machine is perfect, and is a thoroughly reliable and efficient self-feeding and discharging tea-drying machine. There is hardly any possibility of burning the tea, although the temperature used is high. The air used is drawn fresh in from the atmosphere to replace the air saturated with moisture, which is at once discharged from the machine, thus avoiding any stewing of the tea. The space occupied by the machine is less than that of any other turning out the same amount. The labor is very much less, being only two men and a boy for a machine turning out 25 to 30 maunds of *pukka* tea in ten hours. * And please note that this machine is "*not going to*" do this amount of work, but *is doing it* at this present moment.

The reader might suppose that the large amount of tea put into the feeding hopper at one time might go on fermenting. This however, is not the case. It is found that fermentation does not go on in the hopper. This is probably owing to the hopper being placed in the coolest part of the machine, and also to the fact that there is always a slight current of cold air playing about the hopper.

Now as to results. Fermentation is arrested *at once* in the machine, and the value of this is well-known to every tea-maker. The drying by pure unsaturated hot air and the quick arrest of the fermentation give the tea that fine crisp malty flavour so much desired in the market, and the consequence is, that the Cinnamara teas dried by this machine have been tasted by all the experts in Calcutta and reported very highly on; in fact, I may state that a difference in favour of the Jackson's of two annas has been given in the tasters' reports, as compared with another machine in the same factory by a different maker.

As compared with tray machines, the advantage is at once apparent. No removing the trays to turn the tea, with the necessary labor and cooling of the tea while being turned, as the tea is automatically turned in the machine.

In fact, to summarise the whole description, this drying-machine fulfils, as I predicted, every essential of a good tea-drier. I quote from my former description: "The tea is dried by pure hot air, the temperature of which in any part of the machine can be regulated. It requires little attendance. A boy to feed, another to remove the dried tea, and a man to fire and watch the temperature of the air, will be all the attendance needed. It is bound to be economical in its consumption of fuel, as no more air will be used than necessary; and as the flues and drying chamber will be surrounded by non-conducting material, the loss of heat by radiation will be reduced to a minimum; and being of large size, it will be able to turn out a large amount of *pukka* tea." All these conditions have been fulfilled, and there can be no doubt that it is incomparably the best tea-drying machine yet invented, and I have great difficulty in thinking that there can possibly be any advance on it, for, as I said above, it fulfils every essential of a good tea-drier.

And now for the very important question of the cost of the machine. An idea has got abroad that this machine will be costly as compared with others. This is not the case. It is impossible just yet that the future prices can be given, but the inventors will be content with a moderate profit, and intend to put into the market, ready for next season's working a machine which will turn out *at least* 15 per cent more *pukka* tea in the same time than other machines costing the same, besides the great advantages of economy of fuel and saving of labor.

The machine will be made in three sizes to suit various requirements.

Then follow valuations of tea made in Jackson's drier, giving an average of 1/10½ per lb., against 1/9¾ for tea prepared in another drier.

FRUIT CULTURE:

THE MABOLO OF THE PHILIPPINES, ONE OF THE SO-CALLED "VELVET PLUMS" OF CEYLON, THE KAKI, PERSIMMON AND EUROPEAN DATE PLUM.

With reference to Mr. Flamer Caldera's letter (page 349) asking for information on what he calls the "Velvet Plum," our botanical correspondent, having been applied to for information respecting the plant producing this fruit on several occasions during the last twenty years or so, thinks it well to exhaust the subject for the benefit of the readers of the *Tropical Agriculturist*, and to enable us to refer all future correspondents on such "*new products*" to this final notice, if need be, of this exotic tree and its fruits—the Mabolo:—

Sept. 18th, 1884.

This so-called "Velvet Plum" in Ceylon is the well-known Mabolo, a native of the Philippines and Malaya, and introduced to various parts of India and Mauritius, many years ago. But when introduced to Ceylon I do not know as there is no record of its introduction; but I have known the tree and its fruit for the last 20 or 30 years, and, as the finest and oldest I am acquainted with are growing at Elie House, it is likely the tree was introduced by the late Mr. Anstruther, through the late Dr. Wallich, from the Calcutta Botanic Gardens. Trees bearing the peculiar, globular, russet-colored, velvety fruits of this plant are not uncommon in various parts of Colombo and elsewhere in Ceylon, and one of two trees in Stewart Street, Slave Island, is now in fruit, indicating that September is likely to be one of its fruiting seasons.

The tree belongs to Ebenaceæ, the family to which the famous Ebony and Calamander woods and the Kaki and Persimmon fruits belong, and our own closely-allied Timbiri, Sin., *Diospyros glutinosa*, the fruits of which are so well-known to the Sinhalese fishermen, who use them for paying the bottoms of their fishing-canoes and for tanning their nets with.

There is another fruit in Ceylon called the "Velvet Plum" in Colombo. It is the Ketambilla, Sin, the *Aberia Gardneri*, Clos, and *Roumea hebecarpa*, Gardner, native of Ceylon only, at Kundasale, Maturata, &c., but it belongs to the Bixineæ or Arnotta family and cannot be confounded with the one now referred to, though it has a veletty edible fruit. The Velvet Plum, or Mabolo, is well-known to botanists, and has been named, and more or less fully described or referred to, by the following botanists:—*Diospyros discolor*, Willd. Sp. Pl. 4, p. 1108, in 1805; *Diospyros Mabolo*, Rox. Hort. Beng.; p. 4. Lindl. Bot. Reg. t. 1139; Don. Gard. Dic. 4, p. 40 (with full description); *Diospyros melanida*, Sieber, non Poir; *D. embryopteris*, Bojer Hort. Maut. 200, non Persoon; *Embryopteris discolor*, Don. Gard. Dict. 4, p. 41; *Cavanillea Philippensis*, Desrouss in Lam Dict. 3, p. 663; *Cavanillea Mabolo*, Lam. Illos. t. 454; De Candolle Prod. 8, p. 235; Flora of Mauritius and Seychelles, Baker, 199; Flora Brit. Ind. 3, p. 569, in notes on *Diospyros argentea*, Griff. The tree is a handsome one of a pyramidal form, with erect densely pilose branches, and covered with oblong leaves 6 to 8 inches long, silky white beneath, with a densely pilose fruit 2 or 3 inches in diameter, of a russet brown color. To my taste the fruit is very insipid, and in Ceylon it is not worth cultivating except as an ornamental tree, but which, like the *Grevillea robusta*, and some other dense shady trees where birds can roost safely, is very liable to be infested with species of Loranthus. The following account of the Mabolo is from the Dictionary of Economic Plants, by John Smith, A.L.S., p. 254:—

MABOLO (*Diospyros Mabola*), now described as *D. discolor*, a tree of the Ebony family (Ebenaceæ), native of the Philippine Islands, and commonly cultivated in many islands of the East. It has also been introduced into the West Indies. It is a middle-sized tree, having large, firm, coriacious leaves of a light colour underneath. The fruit is like a large quince, and in some places is called Mangosteen. Its flavour is agreeable.

Another very closely-allied plant to this one, and the indigenous Timbiri, Sin., the *Diospyros Kaki*, a native of China and Japan seems to have borne abundant fruit in the Royal Botanic Gardens, Peradeniya, this season for the first time since it was introduced. These fruits, one of the date plums of China, and keg figs of Japan, are dried and sent to Europe. A large cluster of these fruits from the Peradeniya Gardens about the size of a small apple looked very tempting, but tasted as insipid as those of the Mabolo. John Smith has the following notice of it:—

DATE PLUM, CHINESE (*Diospyros Kaki*), a tree, native of China and Japan, where, as well as in India, it is cultivated

* 2,000 to 2,400 lb.—ED.

for the sake of its fruit, which is about the size of a small apple; it is said to be delicious, and is made into a preserve. It has been introduced into Egypt, where it is called Lotus Tree. It has fruited at Kew.

A gentleman who spent several years in Japan spoke to me highly of the different kinds of Persimmon fruits as the very best produced in Japan, and the fruit seems to grow equally well and to be prized highly in some of the Australian colonies.* This is the well-knowu American date plum, the *Diospyros Virginiana*, and the following notice of it is from Mr. John Smith's Dictionary :—

DATE PLUM, AMERICAN, also called Persimmon (*Diospyros virginiana*), a tree belonging to the Ebony family (Ebenaceæ) native of the United States. It attains a height of 50 or 60 feet, and has a rough, hard bark, and unisexual or bisexual flowers. The fruit is nearly round, about an inch in diameter, and of a yellowish orange colour; it is very austere, but after being frosted is edible. These fruits are pounded and made into cakes, from which a kind of beer is prepared, and a spirit is obtained by fermentation and distillation. The tree is rare in this country. One, 40 feet high and 100 years old, may be seen at Kew, which in some seasons produces fruit.

If you extract what Smith says about the European date plum, the subject of the best fruits of this genus will be about exhausted, and I am of the same opinion about them all as I am about the unripe grapes sent from the northern portion of the island either for sale or as presents, viz., that they are insipid *blobs of water!*

DATE PLUM, EUROPEAN (*Diospyros Lotus*), a low-growing tree, native of the south of Europe. It produces a small fruit, which is supposed by some writers to be one of the fruits eaten by the people called Lotophagi.

Surely Ceylon ought to have some of the finest fruits in the world, and it does produce pineapples, such as the West Indian and Mauritius varieties, mangoes, rambutans, plantains, oranges, mangosteens, &c., but, nevertheless, I believe, I am still correct in my belief that in ten acres of well-cultivated ground even in the north of Scotland a greater abundance of wholesome delicious fruits can be grown than in all Ceylon.—Yours, W. F.

We dissent. In the shape of plantains a vast amount of excellent and nutritious fruit food is produced, and our oranges, when allowed to ripen, are very good. There is much room for improvement, however. We append the letter referred to :—

Panadure, 16th Sept. 1884.

My dear sir,—I send you herewith the twig and a tender fruit of a tree growing on my uncle's land at Kalutara, and, as myself and some of my friends wish to know its name, &c., I beg you to inform us of the same through the medium of your journal.

The tree has a straight stem, about 40 ft. in height, with branches spreading round from about 10 ft. above the ground and tapering towards the top.

I have known it for the last 30 years, but it blossomed only this time. This is the only one of the kind I have seen. We call it velvet-tree (villuda-gaha) in Sinhalese.

With my best regards, yours truly,

E. FLAMER CALDERA.

CEYLON PLANTING NEWS: GENERAL REPORT.

COFFEE CROP AND PROSPECTS—LIBERIAN COFFEE—TEA FACTORY AND CULTURE—CACAO.

22nd Sept. 1884.

The new crop of coffee is now ripening up, and the rain which has been pretty general will help very considerably in those districts where the deficiency of moisture has for some months back been very marked. The rain was all from the south-west, with strong winds, and the north-east monsoon, which when I last wrote had put in a very decided appearance, is now here just at present, its more boisterous brother being again in the ascendant.

How much needed this rain was, especially in some parts of the lowcountry, is evident when one learns that tanks in the Kurunegala district, which usually contain 15 inches, do not now show more than 2 inches. There are serious complaints of the quantities of light coffee which are being brought in; but this state of things will doubtless mend. As to estimates, we shall see what we shall see; but it is a sad state of things to hear of an estate which seven years ago had a crop of 14,000 bushels being now estimated to yield only 1,500 bushels. Is it to be wondered at that the pulpers which in the good old past were the planters' pride, working on without a hitch, and hardly any damage to the coffee, are now to be seen tossed aside, unworthy even of house-room, if in any way they interfere with the new favourite, tea.

Still most planters have, I think, a sneaking regard for the product which made the name of Ceylon, and whose power of lifting a man out of a hole into affluent circumstances was manifested over and over again with better weather. I should like to see better prices for coffee, but the retrograde movement in the London market is not an encouraging sign. Albeit, I have heard it whispered by those "that know, you know," that there is a fair prospect before us. The exact words of this murmured communication were :—"Look out for a big rise in coffee." My fervent hopes are that this may be so, and I would try to be sanguine if I could! but, alas! I can't. And, yet, how gladly would I find myself in the wrong, and swing from the depression which settles down when one regards the dark mysterious ways of providence in reference to our old King, to the other extreme of exulting in the smiling face of returning prosperity.

Some people yet believe in coffee, although the faith is fast dying out now. A gentleman who has just returned from a lengthened stay in Java reports extensive new estates being brought into cultivation. No wonder: with such a soil, you can stick a bamboo into it for several feet. All fine black loam, and 15 cwt. an acre is not an out-of-the-way crop. Even the planters there are in keeping with their environment. I question if, at any time in the history of Ceylon, there was ever to be seen a planter visiting his pulping-house with white kid gloves on and a gold-headed stick in his hand yet the visitor from Java assures me that he saw that. We had our days of "pomps and vanities." Claw-hammer coats, dressings for dinner, and a mushroom caste; but we never attained unto the white kid gloves and gold-headed cane. Perhaps it was all owing to our never reaching the 15 cwt. an acre—clearly we have been mercifully preserved.

Liberian coffee, I hear, is doing well about Polgahawela, and an estate in Kurunegala is said to be getting big crops, and paying. This is cheering. Would it were more common.

The large tea factory in Ambagamuwa is making rapid progress towards completion. It has a large turbine for driving the machinery and is going to use the Universal roller. The tea will be fired in a "Sirocco." [And in a Kinmond's drier.—ED.]

Mariawatte is said to be going in for a new set of works next year, which it can well afford.

The very marked results of forking the ground around tea is leading to a considerable demand for digging forks, the three pronged 15" fork being most in request, although in some case the 18" are used. In wet weather the 18" fork is rather heavy; although a fine tool, yet, if a man gets into the way of it, and has the choice of that or the shorter one, I do not find that they elect to change.

Cacao is looking very well indeed, and in a rather famous Kurunegala estate it is doing admirably and without doubt yielding a handsome income to the owner.

The arrangements for drying there are very complete, and the speed with which the cacao is cured is somewhat striking. Into the clerihew a charge of 15 cwt. of cacao is put at night, say at 6 p.m., and next day by noon the cacao has been packed and

* We saw the fruit in Melbourne, growing freely on small-sized trees or bushes.—ED.

delivered at the railway consigned to Colombo. One objection to the clerihew is that the pipes wear out soon, and require occasional renewing, but I have yet to learn of a really better system of curing cacao.

The enemy of cacao, *Helopeltis*, which has lately had Dr. Trimen's attention, and for whose interesting paper on this new pest we all feel indebted, may or may not be a recent importation to Ceylon. Some planters affirm that they have seen it long ago in the jungle in myriads. I know that the late Dr. Thwaites had a fine contempt for the planter as a scentific observer. "You must be trained to observe. You must be trained," the old man used to insist, and doubtless he was right. If the late director has laid it down that the fly is not a native, let those decide who have the right and can do so. I do not pretend to do ought else than record the "gup" of highways and hedges. PEPPER CORN.

NEW FUEL: REFUSE OF SHALE AS A HEATING MATERIAL.

A former Ceylon planter sends us an account of an "experiment with new fuel" at the Forth Bridge Works. The new fuel is the waste or residue left in the manufacture of oil from shale, and, with reference, doubtless, to its efficacy as a heating agent, our old friend writes on the slip: "Save the 80,000 acres jungle for coffee and tea." He means, of course, that the new fuel will render forest reserves unnecessary either for the railway or for tea preparation. The question will be one of cost, and we have good hopes that the new fuel can be delivered cheaply enough to suit us here in Ceylon, in view of the computation that 400 tons of the waste shale product would be not only the equivalent of, but preferable to, 2,000 tons of coal, in the case of a sea-going steamer. We sincerely trust that the new fuel will answer all the expectations formed of it, for, apart from the bearing of the discovery on our local enterprize, we have long felt and expressed our sense of the deplorable opprobrium of modern science involved in the burning of raw coal as a force-generator, volumes of dirty smoke being poured into the air in the process. What a change a smokeless fuel would work in the atmosphere of London, but especially of Manchester and other manufacturing towns of Britain! The invention seems to be in an advanced stage, looking at the letter from the Secretary of the Hydrocarbon Syndicate which follows the account of the experiment at the Forth Bridge:—

THE FORTH BRIDGE WORKS—EXPERIMENT WITH NEW FUEL.

Operations in connection with the two caissons, which have been placed in position at the South Queensferry side of the Forth Bridge works, are so advanced that yesterday a body of men went down into the great pneumatic chamber at the bottom of the south-west caisson to commence the process of excavation for the foundation of this part of the structure. Sir Thomas Tancred and other gentlemen went down two days ago. This chamber is one the floor of which is the sea-bottom. The roof is completely air-tight. As it is many fathoms under the sea, compressed air is continually being pumped into the chamber, by powerful engines placed on the staging just beside the caisson, for the purpose of preventing the water from rising into it. In other words, the constant pressure of air always present in the chamber is sufficient to keep the water from rising. Here men are to be employed day and night, air being supplied by the means just indicated, and light by electricity generated in dynamos on the staging above.

In the working of one of the engines used for pumping compressed air into this chamber an interesting experiment was conducted yesterday—an experiment with the view of testing the substitution of crude shale oil for coal in feeding the furnace. This crude shale oil may be said to be almost a waste substance: the manufacturers extract the oil of commerce from the shale, and what was used at the Forth Bridge works yesterday is the residue collected in the process of distillation. It resembles coarse butter in appearance, and is so crude that it will not burn by contact with a match, a burning coal, or even a red-hot poker. What was used yesterday was taken from the Dalmeny oilworks just above the Forth Bridge. For application it was stored in tanks or reservoirs near the furnace, and these tanks are connected with the furnace by a series of tubes. The grates or fire-bars of the furnace are taken out, and instead of them a cylindrical retort is suspended in the furnace, which retort is surrounded by a spiral tube. From the reservoir of the oil, which is always under pressure, and from a water main, two pipes and valves convey oil and water to the retort and the coil or tube. The retort being warmed by any convenient method, the water valve is slightly opened, and a fine stream passing into the retort is at once converted into steam, which is carried through a superheating coil to a jet or burner underneath the retort, from which jet it issues in a powerful stream by the force of its own expansion. The oil is then admitted in the same manner, and carried by another heating tube to the same jet, which it reaches in a nearly gaseous condition. It is then caught by the superheated steam, and hurled against the convex bottom of the retort, the force of the impact breaking up into finely divided vapour any portion of the oil which the heat may not have already converted into gas. In a short time the retort and heating tubes become red, and now begin a chemical change and nearly perfect combustion. The steam has become a dry gas, or oxygen and hydrogen, which is thoroughly intermixing with heated carbon. The immediate effect of this appears to be the formation of carbonic-oxide and free hydrogen. The force of the jet produces a partial vacuum, and sucks into the centre of these flaming gases a powerful current of air, which apparently completes their combustion, converting them into carbonic acid and water vapour, without smoke, dirt, or residue. The result of the whole process is almost perfect combustion—an immediate and an intense heat which consumes all the products, or, in other words, leaves practically speaking, no residue to be cleared away. The advantages claimed by the inventor of this system over other methods of burning hydro-carbon liquids are, that the retort acts, first as a boiler, or steam generator, to start the fire, while by other methods a second boiler with steam up is necessary; second, the retort is an atomiser, breaking all possible lumps into atoms; third, the retort is a deflector or director of the flame, distributing it equally to all parts of the furnace; and, fourth, its interoal cubic area acts like the air chamber of a pump to keep a steady flow from the jet. Instead of taking moist steam from the boiler to hurl the oil into the furnace, dry superheated steam is furnished by the apparatus itself, and a directed forced air supply added to the natural draught, the result being greater economy and better combustion. The experiments yesterday were regarded as having been perfectly satisfactory, and thus it is probable that the new fuel may be applied to more than the one engine, and employed in various other directions in connection with these gigantic works. Where, as at the Forth Bridge, coal is cheap—possibly about the same cost as that of the crude shale oil—there is still claimed for the use of the latter a decided advantage on the side of economy. The wages of labourers and stokers are saved, for there is comparatively little labour required in connection with the use of oil; there is also an immense saving in the space required for storing purposes; and a saving also in the labour of keeping the furnace and machinery clean, heat with cleanliness being a marked characteristic of this method. Where coal is even moderately expensive a considerable saving must be effected by the use of the oil experimented with yesterday; and in cases in which the cost of transit of coal is very heavy the saving must be correspondingly large. The circumstance that the fire is put out each night by simply cutting off the supply of oil and water is also an advantage on the side of economy; and the circumstance that the fire can be started in the morning by a process extending over five minutes is an advantage on the side of facility in working. It is estimated that the equivalent of this fuel to coal will occupy less than one-fifth the space of coal. It was pointed out yesterday that to an ocean steamer, whose

coal forms one-third of her tonnage, this means an enormous addition to her cargo room, and, consequently, to her earning power. "Of seventy stokers to handle 200 tons of coal per day and put out the ashes, sixty may be left at home. Instead of 2,000 tons of dead weight in coal, the steamer may carry 400. In carrying and consuming large quantities of coal, the matter of ballast is a serious consideration. A hydro-carbon liquid, carried in several tanks, would be expelled therefrom to the furnaces by pumping water into the tanks, the ballast remaining nearly the same." It has been pointed out that the use of such fuel is specially suited to fast-sailing cruisers, which may be required to stay at sea for a long period, without being necessitated to put into port or station for coal. As has been indicated, yesterday's experiments were so successful as to justify the belief that an extension of the method described at the works is almost certain to follow, to be attended it is believed, with great advantage in various ways. This is the first occasion, it is stated, on which this cheap oil refuse has been so applied in Scotland. The inventor of the method, Mr. E. C. Burgess, conducted the experiments, which were watched with much interest by Sir Thomas Tancred.

EXPERIMENTS WITH NEW FUEL.

Sir,—Referring to the excellent article in your impression of last Thursday, headed "The Forth Bridge Works—Experiments with New Fuel," permit me to point out that the process referred to is not in the experimental stage your correspondent seems to imagine. The hydro-carbon process described in the article is the original invention of Dr. Holland, of Chicago, and his process has for some time been successfully employed in America competing with coal on locomotives. Engines worked in this manner are now running on the New York, Lake Erie, and Western Railway; it is also in use for domestic and many other purposes. The patent rights for Europe are in the hands of an influential syndicate, whose engineer, Mr. E. C. Burgess, has succeeded in adapting the Holland process to the shale and coal oils of Great Britain and the crude petroleum found in vast quantities in Europe, and not necessarily to only Scottish oil as mentioned by your correspondent. The employment of the process at Forth Bridge Works is somewhat beyond an experiment, as the apparatus has been during the last eighteen months thoroughly tested at the syndicate's works in London as well as put into competion with coal at the long trial, at Messrs. Oliver & Co.'s engineering works, Chesterfield. I can fully endorse the other remarks of your correspondent as to the magnitude of the invention, and I look before long to see the process rank with coal and electricity for giving motive power. Apologising for taking up your valuable space.—I am, etc., ARTHUR RADFORD. Secretary of the Hydro-Carbon Syndicate, Ld., 18 Lawrence Pountney Hill, E. C.

TEA CULTURE AND "JÂT."

The correspondent who writes (page 352) on this subject seems to know so much about the peculiarities of best jât tea, that we suspect his object in writing is more to denounce some malefactor who palmed off inferior seed on him as best hybrid, than to obtain information respecting varieties of the tea plant. We attempted to give him the information he seemed to desiderate, and, in resorting to the *Tropical Agriculturist*, he might have found something better to refer to (he talks of "an article" as it by the editor!) than a letter by a Mr. Stuart Cranston, a Glasgow grocer, who, having dealt in China tea all his life, naturally exalted it above the superior Indian tea. As to Col. Money's views, it is better to take them at first hand from the latest edition of his own book, which we reviewed at great length recently. We quote as follows:—

The indigenous tree has a leaf of 9 inches long and more. The leaf of the China bush never exceeds 4 inches. The indigenous leaf is a bright pale green, the China leaf a dull dark green colour. The indigenous "flushes," that is, produces new tender leaf, much more copiously than the China, and this in two ways; *first*, the leaves are larger, and thus if only even in number exceed in bulk what the China has given; and *secondly*, it flushes oftener. The infusion of tea made from the indigenous species is far more "rasping" and pungent" than what the China plant can give, and the tea commands a much higher price. The young leaves, from which alone tea is made, are of a much finer and softer texture in the indigenous than in the China; the former may be compared to satin, the latter to leather. The young leaves of the indigenous, moreover, do not harden so quickly as those of the China; thus, if there is any unavoidable delay in picking a flush, the loss is less with the former. In the fact that unpruned or unpicked plants (for picking is a miniature pruning) give fewer and less succulent young leaves which harden quicker than pruned ones, the two varieties would seem to be alike. The China variety is much more prolific of seed than the indigenous; the former also gives it when younger, and as seed checks leaf, the China is inferior in this as in other respects. The China is by far the hardier plant; it is much easier to rear, and it will grow in widely differing climates, which the indigenous will not.

A patch of indigenous with a mature flush on it is a pretty sight. The plants all appear as if crowned with gold (they are truly so if other advantages exist), and are a great contrast to the China variety if it can also be seen near.

I have now, I think, pointed out the leading characteristics of the two original varieties of the tea plant, and it stands to reason no one would grow the China who could get indigenous. But the truth is a pure specimen of either is rare. The plants between indigenous and China are called "hybrids." They were in the first instance produced by the innoculation, when close together, of the pollen of one kind into the flower of the other, and the result was a true hybrid, partaking equally of the indigenous and China characteristics; but the process was repeated again and again between the said hybrid and an indigenous or China, and again later between hybrids of different degrees, so that now there are very many varieties of the tea plant—100 or even more—and no garden is wholly indigenous or wholly China. So close do the varieties run, no one can draw the line and say where the China becomes a hybrid, the hybrid an indigenous. Though as a rule the young leaves are light green or dark green as the plant approaches the indigenous or China in its character, there are a certain class of bushes all hybrid, whose young leaves have strong shades of crimson and purple. Some even are quite red, others quite purple. These colours do not last as the leaf hardens, and the matured leaves of these plants do not differ from others. Plants with these coloured leaves are prolific.

Colonel Money takes the position that it would have been better if China tea had never been introduced to hybridize the superior Assam plant. Cultivation would not have been so widely extended, but the produce would have been superior. Baildon, in his book, takes the more general and more correct view, thus:—

Taking India as the real home of tea, there was, of course, primarily, but one kind of plant. But I am reminded, in thus writing, of the botanical classification of the *Thea viridis*, and the *Thea bohea*. I was recently informed by a well-known professional botanist, that it is still almost an open question as to what is the difference between the two plants; and that there is no doubt as to their having originally been one and the same. In India, making either green or black tea depends upon the will of the planter.

But all writers on Indian tea have been obliged to give three classes of the plant—the indigenous, the China, and the hybrid; though according to the theory I have mentioned, the China plant is but a deteriorated specimen of the pure (Indian) plant. But centuries of varied cultivation in a climate not its own, and no small amount of neglect, have made this wandering offshoot a distinct variety, although ranking botanically partly under the same name as its parent, *Thea bohea*; so distinct, indeed, as to have

assisted in the production of an entirely new plant—the Hybrid.

The introduction of China tea (in seed) into India, has frequently been deplored, as the plant is not a particularly remunerative one to cultivate. But few evils are devoid of some indirect good; and although the China specimen is a disagreeable thing to grow, and its out-turn more generally unsatisfactory than otherwise, the hardy nature it has blended with the pure Indian plant is a very wholesome addition.

It is more satisfactory to cultivate good hybrid than either indigenous or China plants. The blended natures have resulted in a vigorous and hardy specimen, more suited to the climates in which it has been planted, than is the pure Indian variety, yet retaining a sufficiency of its original character to make its culture remunerative. A good tea climate must be humid. The atmosphere in the forest home of the Assam tea-plant is sometimes so moist as almost to give the idea of solidity. Hidden in the jungles where the rain fell in torrents, and where he dense undergrowth prevented the sun from drying up the ground, the tea-plant originally lived in an atmosphere which was always damp But it was discovered in its wild luxuriance, protected by almost impenetrable jungle; and British energy and enterprise brought it out of seclusion. It was taken away and planted in open spaces, deprived of the shelter of its giant neighbours, and exposed to the direct action of the sun; and having a supply of moisture only when it rained. it forgot how to vegetate as it previously had. So it was found that what had been healthy and vigorous as jungle, was apt to be delicate and fragile as a cultivated plant. It is because of this, that the propagation of the alien (China) plant, has not been without its good. The sturdy, sluggish nature of the Indo-Celestial species, has blended harmoniously and advantageously with the pure Indian variety; and what was absolutely necessary for the successful extension of the Indian tea industry—a plant more prolific than the China, yet less delicate than the indigenous—nature has bountifully given in the hybrid.

Tea of the hybrid class is being cultivated remuneratively at the present time in places where, I am certain, the indigenous plant could not live. Tea of the same order is also thriving and paying, after living through neglect and harsh treatment which would have killed indigenous tea in its infancy. Had the deteriorated (China) plant not been brought back to India, and allied itself with its old species, I am convinced that the enterprize of *Indian* tea cultivation would have been confined to a very considerably less extent than that at which it is now carried on.

"JÁT."

DEAR SIR,—I am afraid your interesting extracts from "Cooper" on "Brick Tea" did not impart much information on "ját." Since writing I have come across an article* in the *Tropical Agriculturist* (March 1st, 1882, page 819), in which Colonel Money's Prize Essay on Tea Cultivation is largely quoted. I copy a few of his remarks on jât. which will bear republishing, now that so many more are interested in the question than when it first appeared in your columns. He says:—

"The indigenous tree has a leaf nine inches long and more; the leaf of the China bush never exceeds four inches. The indigenous flushes much more copiously than the China: the leaves are larger and it flushes oftener. The infusion of the tea made from the indigenous species is far more rasping and pungent than what the China plant can give. The India tea is vastly superior to China, and commands a much higher price at home, but it is still very inferior to what it would have been, had not China seed been so recklessly imported and distributed in India."

This last sentence of course refers to Assam hybrids, *i. e.*, indigenous spoilt by China. Still, admitting that a good hybrid more closely allied to indigenous than to China is a good plant and perhaps better suited for our hills than pure indigenous would be, there is no escaping from the unmitigated denunciation of the pure China jât, or the hybrid closely allied to it: "It does not flush so copiously or so often, and it lowers the value at home." This surely is enough to damn it. But how are we to tell it? That was and *is* my question; and in the "hundred different" hybrids, where are we to draw the line and say "This is Assam hybrid and this China hybrid"? Are there not degrees of badness in the pure Chinas as in the hybrids? I have, unfortunately, in my igoorance, got in very fair looking plants pronounced to be pure China, and I have also got things that don't resemble tea at all: awful looking things while they are young. Will they improve with growth? There is no *mistaking* a good jât: bold, light green leaves more or less beautifully marked as though they had been artificially embossed; edges well serrated, then right round the leaf, from the edge a quarter of an inch deep, dimples and swellings, from which ornamental border deep gutters run to the midrib, the color of the leaf being a golden green, and in shape nearly as broad as long, with a teat point. I take this description from a leaf of my best Assam hybrid plants grown from India seed.

Against this I have some others in color a dark green or sickly yellow, leaves small and narrow tapering evenly to a point (no teat point), with no markings on the leaf, which is *perfectly smooth*. Whereas some that I have with a larger leaf, pronounced to be pure China, have distinct gutters from the midrib and *all* are serrated more or less. Ought these *smooth* narrow-leaf things to be allowed to grow?

Further on, in the article above alluded to, Col. Money in many ways insists upon the vast superiority of Indian over China teas; but the said article has an unexpected and curious ending. I quote one sentence:—"Judged by its effect upon the human system, and not by its price in the markets, we beg humbly and with considerable diffidence to contradict Col. Money by declaring our opinion that *China tea is vastly superior to Indian tea*"!!! Which is true?*

V. S.

* Certainly not an article: only a letter by a Glasgow grocer.—ED.

FRUIT CULTURE: GROWTH OF TREES.

We hear that some of the estate proprietors on the Shevaroys and other coffee producing tracts in the presidency have recently, owing to the fact that coffee has not given such fair outturn as it does in favorable seasons, begun to devote some attention to the planting of fruit trees which grow luxuriantly in many parts of the presidency and amply repay the outlay incurred in their growth. The growth of fruit trees for avenues along public roads has been encouraged in some districts, and along many of the principal trunk roads many large fruit trees may be seen. It is evident that the old revenue officials and land-holders knew what they were about, for the tamarind, the mango and the jack tree have been most extensively planted. In those parts where the trees have grown well and yield fruit of good quality, the local boards may safely expect to obtain a small revenue. It is, however, to be regretted that more is not done in this direction, and that along many of the public roads in the districts, and especially the newly-formed roads, as much care is not taken, as used to be the case in former years to grow good species of fruit trees whose umbrageous branches afford shelter to passengers and whose fruit may be sold for the benefit of the road or avenue fund in every Local Fund circle. What the revenue officials might well encourage and carry out, owners of private estates have now set about to achieve, and it is hoped that success will attend their endeavours. The jack and the mango

* Our correspondent, who generally knows how to express his ideas clearly, has taken an over-dose of tea. He in words affirms that the statement of the prejudiced Glasgow grocer is true, while he really meant to ask Which [statement] is true?"—ED.

are among those that give a fair return on outlay in a few short years. Many years ago coconut plantations were all the rage in Madras and in the adjoining suburbs, and every Hindu inhabitant, with moderate means at his disposal, managed to purchase or form a small coconut garden from the revenue of which he was able to support himself and family. The coconut is a valuable tree and the revenue derived from a well stocked garden years ago was large. That was the time when coconuts were extensively used in the manufacture of oil and when the juice of the tree, known as toddy, was largely adulterated and drunk by the poorer classes of natives. But since of late years, toddy is evidently not so largely consumed as it once was and coconuts are not so extensively used in the manufacture of oil, because with the importation of kerosine oil in thousands of cases from Europe and America, coconut oil is not largely consumed but the price is as high if not higher than it was some years back.

Mango and jack are among the fruit trees that bring in a fair return on outlay and hence their cultivation finds favor among European owners of land in the districts. The coconut has to be largely supplied with water, especially when the trees are set apart for toddy. But mango and jack require care for a few years, after which the rainfall is sufficient to help them to produce. If the trees are well looked after and manured the return is largely and in fact more than compensates the outlay incurred. The Salem district is one of the most favorably situated in the Madras presidency and has the reputation of producing very superior qualities of certain descriptions of fruit. Salem mangoes and oranges are the most edible, and it is no matter for surprise that owners of coffee estates have resolved to give some attention to the cultivation of fruit trees.—*Madras Standard.*

TEA: DEMAND FOR INDIAN TEA IN AMERICA.

While in New York I discussed the prospects of our Indian tea trade with the agents of the Calcutta Tea Syndicate. They were very sanguine of our ultimately securing a good share of the American consumption if moderate shipments of good teas are kept up and Indian exporters are not discouraged by the comparatively poor prices which have been so far paid. They instanced the case of Japan, which did not obtain the strong position it now holds in regard to the supply of tea to America without a severe struggle, and in the face of losses continued for a good many years. Some speculative purchases of Indian tea were made in New York about the time of my visit for resale in London which produced a bad effect both in London and Calcutta, but these were made light of. The hopeful features of the trade as pointed out to me, were that, so far as black teas go, the Indian producers have the field to themselves, there being no other black teas imported into America which at the price can at all compare with our Indian growths. The reason American taste has hitherto run so much on green teas, in preference to black, was said to be simply on account of the inferiority of the black teas hitherto offered and not from any prejudice against black teas *per se*. It was also found that wherever the Indian tea sold in New York got into consumption, (and the aim of the Syndicate agents was to secure this,) buyers almost in every case repeated their orders for it, which is the best possible proof that consumers appreciated it. The Americans need to learn a great deal as to the art of blending and infusing teas, and if an Association were started to supply a good article, and got the hotels initiated in the art of using it properly, it would be a paying speculation and a great step gained. The filthy decoction usually served at American hotels under the high sounding name of English breakfast tea is enough to make any one who knows what a cup of good tea really is, turn away in disgust, and it is little wonder coffee or milk are more in favour. American buyers like a good looking tea, and lay more stress on appearance than liquor, so that large leaved varieties, even although with good liquors are less suitable than the small leaved China sorts. The finest teas are also at present thrown away on them. By and bye, I have no doubt, they will be appreciated and command their value, but at present medium to good teas, not too high priced, are what they want.—*Correspondent of Englishman.*

COFFEE, SUGAR AND CINCHONA IN JAVA

are thus noticed in extracts from Batavian papers translated for the *Straits Times* :—

Batavia, 23rd August.—In coffee-growing the Government is trying more and more to encourage mechanical preparation of the berry among the people, both for saving labour and furthering a better manipulation of the product. In Passarnan, where the increasing crops and the greater demand for labour in consequence of the spread of private plantation enterprize have shown the need of a more liberal use of mechanical preparation, the two Government pulpers now at work will this year be increased in number by setting up 13 additional ones, at an estimated outlay of 100,000 guilders. It is noticeable in the official report of an expert, that the climate of Mid Java is more suitable for cinchona officinalis than that of West Java. Flourishing plantations of this variety are met with, for instance, around Wonosobo in the province of Bagelen at a height of from 4,000 to 5,000 feet above sea-level. In growth these trees far excel those within the gardens at Dodabetta in the Neilgherries. Advices from Deli state, that the laying of the railway there was being actively proceeded with. As is well known, this railway connects Medan on one side with Labuan, the present customs station, and Belawan, the anchoring place for large steamers, and, on the other side, with Deli Tuah, the former chief town of Deli; while by a side line 25 kilometres long, Timbang Langkat, the chief town of Upper Langkat, is connected with Medan. The greatest work will be a bridge about 400 yards long and wholly built upon iron piles screwed into the ground, which, when finished, will only find its match in the splendid viaduct over the Chitarum river on the Java State Railway. The line between Medan and Labuan will probably be open for traffic before the end of this year.—Batavia *Handelsblad.*

Cinchona.—Considering the feeling of depression now general among a large portion of the European population of Java in consequence of the low rates ruling for sugar and coffee, and the prevalence besides of leaf-disease, it is a gladdening phenomenon that Java, in any case, has still cinchona growing available, which is both profitable and promises much for the future. The enormous prices still realized for good sorts of cinchona bark, notwithstanding the fall in the price of quinine, fully bear this out. At the sale of cinchona bark held in Amsterdam in June last, the highest price, 302 cents per half kilo, was brought by a consignment of that article from the Pring Ombo estate in the province of Pekalongan. This cinchona bark, so we are informed, was from trees thinned out of a four years old plantation of typical Ledgeriana. When it is taken into account that cinchona trees four years old are far from being full grown, and that according to Mr. Bernelot Moens, eight years old Ledgeriana trees yield each half a kilo of dry bark, while also the percentage of quinine in full-grown trees is greater than that in four years old trees, it may safely be taken for granted that the Pring Ombo estate has furnished proof that Java possesses in cinchona cultivation, carried on judiciously in good soil, at least one profitable branch of cultivation.—*Locomotief*, 9th Aug.

AGRI-HORTICULTURAL SOCIETY OF MADRAS : FRUIT TREES AND RUBBER.

From the proceedings of this Society we quote as follows :—

Read letter from Dr. Trimen, dated Peradeniya, 27th May, 1884, acknowledging with thanks the Society's neat little volume of Proceedings, making his set complete; expressing his pleasure at hearing that the Society is getting out a new Catalogue of the plants in the Gardens which will be most interesting and useful, as the Society has a "peculiarly interesting collection"; pointing out that he noticed in January

while in the Society's Gardens that the Calabash Tree labelled "*Crescentia cujete*" is the winged petioled one, *C. Alata** (sometimes placed in the genus *Parmentiera*); suggesting that the Society has probably the true *C. Cujete* also, though he did not see it, and that if not he can send it; asking for seed of the *C. Alata*, which he has not; apologising for the delay in sending the Bread-fruit Trees, of which about a dozen had been propagated for the Society, but by some mistake during his absence were sent to the north of the Island, whither he had also intended to forward some; and promising soon to have another lot ready in the low-country, where they are propagated. Recorded with many thanks.—Read the following extracts from a letter from Messrs. William Brothers, Merchants & Planters, Henaratgoda, Ceylon, dated 22nd May, 1884:—"We have tapped a Ceara Rubber tree of six years age at the beginning of April. Three days successive tapping by an ordinary knife gave 8¼ oz. dried rubber. Ceylon Ceara rubber has already been valued in London at three to four shillings per pound. The operation can be done twice a year. Three hundred Ceara trees to the acre at 12 feet apart, at one pound rubber per tree—per annum 300 lb.—pays at R1, R300; coolies' pay for tapping, superintendence, and other expenses, per acre, per annum, say R100; profit per acre per annum, R200. Certainly this is very encouraging, considering the little outlay it requires. The quantity of rubber increases yearly with the age of the tree, but our experience shows that it is not advisable to tap Ceara trees under five years age." * * * * * "Ceara Rubber seeds can be grown without filing, as follows:—Keep the seeds in cold water for six days, put in the nursery covered about half an inch with soil, about 2 or 3 inches apart, and water twice a day—morning and evening—in dry weather. The nursery should not be shaded, or the seeds will perish. Seeds will begin to germinate one month after planting from time to time, and will take from two to four months to complete the germination." Recorded with thanks.

Certainly, Messrs. William Brothers of Henaratgoda are much more sangnine about Ceará rubber than most European planters are. We add the following:—

On 19th July, 1884, the Superintendent cut a mature fruit of *Landolphia*, sp., from one of the plants growing up one of the shade trees in the nursery,† and has successfully preserved it, with leaves and flowers, in spirit. Resolved, that this specimen, being probably the first fruit of *Landolphia* matured out of its native country, be sent to the Government Museum, and that Sir John Kirk be informed of the success of his efforts to introduce the plant.

THE PROSPECTS OF ENGLAND'S TROPICAL COLONY.

AN INTERVIEW WITH A CEYLON JOURNALIST (MR. JOHN FERGUSON).

(From the "Pall Mall Budget," Sept. 5th.)

"We have not now 'all our eggs in one basket.' At present the city will not look at Ceylon as a field for investment. Money is scarce owing to the fall of the Oriental Bank, and our credit has been greatly damaged by the collapse of the Ceylon (more properly the Mauritius) Company. It should be known, however, that in our climate, roads, railways, cheap free labour, we have every encouragement for tropical agriculture in Ceylon. Our natives are being so rapidly educated that by 1900 A.D. English will practically be the language of the majority of the people. Colombo is the centre of the Eastern world, thanks to Sir John Coode's new harbour; and capital judiciously invested in tea and cacao culture especially, is as likely to bring a good return as any agricultural enterprize I know of anywhere." Such is Mr. Ferguson's summing-up of England's tropical colony. He is inclined, it will be seen, to take an optimistic view of Ceylon and its future, but he speaks with the accumulated experiences of twenty-three years' residence in the colony. Then he has the numerous correspondents of his papers, the *Ceylon Observer* and the *Tropical Agriculturist*, scattered all over the tropical world where English planters are at work; some reporting on tea in Assam; on planting prospects in Java and Fiji; on the new Liberian coffee in West Africa; and on planting in Brazil; while he himself has just been making the all-round the world trip, visiting California and Florida *en route*. "Nowhere is tropical agriculture so thoroughly studied and experimented on as in Ceylon."

YOUNG MEN WANTED.—"We now ask for young fellows of the right sort—even public schoolmen, university men—any one with pluck and energy who comes determined to fight his way against all odds. Do not mistake me. We do not want to be flooded out by thriftless ne'er-do-weels, who have failed at everything they have turned their hand to, but resolute chaps with a little capital to invest, though they must first serve an arduous apprenticeship, for there is no royal road to tea-planting. No young fellow should come out without some money and letters of introduction to planters or merchants. A tropical country is so different in its conditions from Australia and New Zealand, where a man can turn to at once. Let us suppose our model young man landed at Colombo and despatched to a station to serve his novitiate. In some cases he might have to pay from £50 to £100 a year for his board and training, but if he shows any aptitude for his work and is a willing horse, he would well repay his cost for food and shelter."

THE FUNGUS SCOURGE.—"The story of the coffee blight is soon told. A few years ago, coffee alone was seen over hundreds of square miles of hillside and valley, eastward, south, and north of Adam's Peak. Then in 1869 the fungus appeared, and year after year it did its deadly work, and half ruined us. Here are some figures which put the matter in a nutshell. Take the coffee production from 1847 to 1883 now. You have in 1847 an acreage of 45,000, with an export of 200,000 hundredweight; in 1857—85,000 acres, and 450,000 hundredweight; in 1867—168,000 acres and 868,000 hundredweight; in 1877—272,000 acres, and 926,000 hundredweight; in 1883—174,000 acres, and 265,000 hundredweight; whilst 1884 is expected to give from 360,000 to 400,000 hundredweight. I think we may fairly say that the point of depression has been turned, if the estimate proves anything like correct."

TEA WILL SAVE US.—"What happened after the coffee blight became serious?" "Why, naturally enough, many of the plantations were deserted, the capitalists took fright, superintendents were thrown out of employment, and set off to other countries. There was a regular migration to Northern Australia, Fiji, Borneo, the Straits, California, Florida, Burmah, and elsewhere. I should say that out of our 1,700 planters we lost at least 400 in this way. In Northern Australia, at Port Darwin, three or four of our Ceylon planters have planted coffee and cinchona; in California some are busy with vines and oranges. Some have gone to Florida among the orange groves; but a Floridan orange grove requires twenty years to come to full maturity, though the trees bear long before that, say in six years. There is a ready market in America for the fruit, but a man requires to work hard there and to know his business before his speculation is likely to prove remunerative. But our indomitable planters, who stuck to their posts, began to turn their attention to other products—tea, cinchona, rubber, cacao; some 175,000 acres of coffee being still under cultivation. Now the coffee planter runs belts of rubber trees and cinchona between his coffee bushes, thus helping to check the spread of the dread coffee fungus. I think the statistics show that the scourge is abating; but whatever comes of coffee, Ceylon will become a great tea-growing country within the next few years. When the 35,000 acres of land now under tea come into full bearing, in three or four years we expect to export ten million pounds. Some day Ceylon will have 150,000 acres under tea, and an annual export of sixty million pounds and upwards. Home capitalists have only to say the word. From 482 pounds of tea exported in 1875-6, the amount in 1882-3 reached a million and a half pounds. The yield of cacao for this year is likely to reach 10,000 cwt. Last season we exported 7,000,000 pounds of cinchona bark, this year it will be 10,000,000; while of cinnamon and palm tree products (grown chiefly by natives) we ship nearly a million sterling's worth. The Sinhalese and Tamils are quite ready to follow the European planters in reference to the new products of late years being introduced into Ceylon. They have planted

* This error had been already discovered by the Superintendent and the label removed.

† *Vide* page 263, ante.

the cinchona, cacao, and rubber trees; but especially are the Sinhalese likely to become extensive growers of the tea plant."

THE LAND AND THE CLIMATE.—"Now is the time to buy land, for we are on the turn after years of depression, and such land as you can now buy for 16s an acre, may in a year or two be doubled or trebled in price. Just as was the case in the years between 1868 and 1875, when every one was 'going into coffee,' and forest land sold for £20 an acre in some districts. Since 1833 some 1,300,000 acres of Crown lands have been sold (to Europeans and natives), at an average price from 1833 to 1844 of 10s 8d. from 1844 to 1883 the average has been 35s., and the upset price now is 16s. There is no land tax, except within the areas of the towns." "And what about the climate?" "Delightful—for the tropics most healthy, and not much hotter than it has been in London during the past few weeks, even in March and April. Most of the planters and their assistants enjoy the best of health, though of course pioneers and those who have to work through new forest and in the lowcountry, often suffer from malarious fevers. But then have you not the cool mountain station to fly to as a restorer? There is Nuwara Eliya and Bandarawela, on the plateau of Uva Principality, where you get coolness, health-laden breezes—and I have even broken the ice in my water jug, in a Nuwara Eliya cottage. Given a change now and then, good food, care, and temperance,—a European is as well off as regards climate (some might say better) than at home here."

FREE LABOUR.—"One of our greatest advantages is 'Free labour.' Close at our shores are the twelve million coolies of Southern India, whose average earnings are between £3 and £4 a year each. Yes, and he is able to live on it, too, and to support a wife and family. From this vast source we draw our supply of labourers, and fine, well-trained, diligent fellows they become. They come over with perhaps a wife and three or four children; they are engaged for a period, a month's notice sufficing to terminate the contract on either side. There is a hut ready for them, with a bit of ground for a garden, in which they grow vegetables and so on; the planter gives them clothes and food until they are able to repay him out of their earnings. Their wages average from ninepence to a shilling a day for a man; a woman can make about 7d., and a child 5d., so they are well off; they save money, and when they go back to their own village in a year or two's time they have probably some five or six pounds in their pouch. This the careful coolie invests in a piece of land, which, on his return to the Ceylon plantations, he leaves in charge of a relative or a friend until he returns again. Our Kandians, or highlanders, are splendid axemen, and it is they who do the felling of our forests and the clearing of the land ready for planting. Then the South Indian coolies do the digging and planting. The land, by the way, lies generally on timbered slopes. The axemen begin at the bottom, cut each tree half through, and work up to the top. The highest fringe is cut clean through, and with its weight brings down the rest of the slope in the fall. The Sinhalese themselves refuse to do any agricultural work for Europeans. It is beneath them. They are our carters, employed in taking the tea and coffee, and so on, from the stations to the coast. If I remember rightly there were some 13,000 licensed carts a year or two ago. The Sinhalese are also our boatmen and artisans and domestic servants. Now, many of our Sinhalese and Tamils are wealthy. One, indeed, is the richest man on the island, with an income of some £200,000 a year or more. Some of the coolies, I must confess, are sad thieves. You may of a Sunday meet a man and his wife on the road, one of them carrying a cock, the other a hen. The birds are all their portable property, which they were compelled to take with them while visiting some friends, lest they should be stolen."

CEYLON RAILWAYS.—"The cost of the Colombo and Kandy Railway, of 74 miles, was £1,740,000. Then an extension to Nawalapitiya from Peradeniya, 17 miles, was opened in 1874; and an extension from Kandy to Matale, 17½ miles, in 1880. Besides these, a seaside line has been constructed from Colombo to Kalutara, 27½ miles. In August, 1880, the first sod was turned of an extension from Nawalapitiya for 42 miles to Upper Dimbula, whence it was intended to be carried 25 miles farther to Haputale. Altogether about 180 miles of railway, all on the 5½ ft. gauge has been opened or are under consideration. But there is one grievance which I should like to point out concerning these railways. The length of forty-two miles from Nawalapitiya to Upper Dimbula will probably be opened in May, having cost £900,000 of money. But then they are going to stop short instead of pushing on, as was proposed, to Haputale, the real terminus, with new traffic, which is only twenty-four miles further, which would cost £400,000, and open up a vast amount of splendid country, which at present is compelled to send its produce round by road, a distance of 200 miles—a road which is subjected to floods, too, to say nothing of the delay and cost."

THE PLANTER AT WORK.—"Let us suppose that a young man has learned his business, and has a thousand or two of capital. He buys 200 acres at 16s. an acre. He would begin by opening up, say, twenty-five acres his first year, clearing, draining, and planting. Then, in his second year, he would prepare another twenty-five acres. Up to and including the third year his outlay would be about £20 to £25 an acre. In his third year there would be a crop of tea-leaf—a small one. In the fourth and fifth years he might expect, supposing that he is lucky, to have a crop of tea of 400 lb. to the acre, which he would lay down in England at 9d. a lb., which would produce in the market from 1s. 3d. to 1s. 11d. a lb., thus leaving a margin of 6d. profit. Then he would advance, not laying out too much capital to start with, but gradually feeling his way. All the year round tea requires one man per acre, in crop time a fuller force. It is hard physical work, though there may be no absolute manual labour. At five in the the morning the bugle sounds for all hands, the planter comes down to the muster, the coolies go off to their work, the master has his coffee and follows them, going on foot of course, from point to point, supervising and directing, and at 11 a.m. he returns to his breakfast. Until 3 p.m. he remains indoors, attending to business matters, going out again for another tour of inspection. And so the days pass." "Snakes?" "The clothing is a great protection against snakes, and during the last sixty years I don't think there has been one case of death among the whites. The natives, of course, have no protection from clothing, and are more careless. In Ceylon our coffee machinery for pulping, for skinning, for drying, has been brought to a state of perfection, and the machines manufactured at Colombo are known throughout the tropics. It is this attention to improvements that has helped us so materially. Our planters are men with ideas, which they are quick to put into force. So it is with the new industries—tea, cinchona, cacao—the machinery for their preparation is being improved every day. You see Ceylon is a comparatively small country, and the planters are able to compare notes. A hears how B is doing this, he tells it to C., they have a talk about it, and so the matter grows. Each district has its little centre (not to mention the health resorts on the hills), where there is a club and other facilities for the intercommunication of ideas."

THE WAYS OF THE HEATHEN CHINEE.—"On my way from Singapore to China I fell in with a Sumatran tobacco-planter who had imported Chinese coolies at a cost of £7 to £10 a head, on an engagement of a number of years. Smallpox broke out among them. Now a Chinaman prefers death to disfigurement; he has no notion of revolving through endless cycles with a pitted face, so they took to suicide, and every morning the overseer came in with his report: 'Another thirty pounds gone, sir. Three more of 'em found hanging to a tree just now.' This was a serious difficulty. So at last the planter issued a proclamation to the effect that the body of the next dead Chinaman would be cut into pieces. This device stopped suicide. Another curious fact respecting the peculiarities of the Chinese is worth mentioning. When they sign articles on board ship one of them is that if he dies on the passage his body shall be embalmed and sent back to China. In the boat coming home one of our stokers met with an accident. The doctor said the only chance for him was to cut off his leg. 'No, no,' said the stoker and 'No, no,' chorused his comrades. But in a day or two mortification set in, and the leg was sacrificed. The man died, and his friends were horribly savage at the desecration wrought by the doctor's knife and saw. But

they made the best of it, and embalmed the mortified leg with the dead body of poor John. The Chinese in the Straits earn, if they are good workmen, about 4s. a day. Perhaps, we have three Chinamen all told in Ceylon, but it is curious to notice that four days' steam from Colombo to Singapore you are virtually in China, for the Chinamen are gradually filling it up. Of course there is much to be said on both sides—but the Californians, so far as I saw, miss their Chinese servants sadly—in fact, a Chinaman is at a premium. In my opinion the time had not come to stop Chinese immigration. At present only tradesmen are allowed to enter the country, though for every Chinese coolie who dies one is allowed to take his place. A big business is done in certificates from all I can hear. Why, I heard that one of the most violent of the anti-Chinese agitators still kept to his Chinese servants. He is not a true patriot, like the Englishman who refused to eat slave-grown sugar. Some two or three years ago a Queensland planter engaged 500 of our Sinhalese to go to his sugar plantations. They went, much to our surprise, for such a thing as Sinhalese emigration was unknown. They proved a bad bargain, for they were gaol-birds of the worst type. Few of them ever found their way to the plantation, many were absorbed in the towns, whilst a few found their way back home."

AN OPENING FOR ENGLISH GIRLS.—"There is just one word of advice I should like to give to fathers and brothers. To the latter, if you go to Ceylon—or to any other colony, for the matter of that—take your sister with you. England is overstocked with women, who are clamouring for work and votes and husbands, too. Now England is sending out some of its best blood to its distant possessions. Why should the young men go and not the young women? I am convinced that the presence of his sister would have saved many a young fellow, in the pioneering days, from drink and ruin, in Ceylon alone, if she had been there to look after his bungalow and minister to his wants. Fellows used to come in from a hard day's work on the slopes, fagged and weary, to their bungalow. There was food for them prepared by native servants, but it was often not fit to eat. So some went to the beer or brandy for consolation. Things are better now, and ladies more numerous; but still, in colonizing, sister and brother may well go out together. But there is no need for me to expatiate on the advantages of my proposal."

"What do you think of the prospects of the North Borneo Company?" I asked Mr. Ferguson, as he rose to go. "I cannot say from actual experience, but we have one or two correspondents there from whom we hear now and then. It took Ceylon seventeen hard years of pioneering before we began to think that success would be possible, and North Borneo is yet a very young country. There are at present a few plantations of tea, coffee, and cinchona scattered along the coast, while collectors are at work in the interior gathering ivory and minerals. It is like other colonies—it needs capital and men."

KEW GARDENS.—"I cannot, by the way, over-estimate the value of the work which Sir Joseph Hooker and Kew Gardens do for us, not only for Ceylon, but for all the tropical countries wherein fresh productions are being tried. He has correspondents and collectors in all parts, and if any one wishes to try experiments he has only to write to Kew for advice and specimens, which are forwarded to him from the gardens. You might think that it would be easier for us to send to the country where the plant or fruit was indigenous rather than to England, but the difficulties would often prove too great. Kew is of vast service to the planters in many respects." "The military force," said Mr. Ferguson, in conclusion, "stationed in Ceylon, costs us £120,000 a year, or 10 per cent of our revenue. Now, why should we be compelled to expend this sum on British troops we don't want. It is a serious grievance. You use Ceylon as a convenient centre, from which you may draw in case of any little war in India, in China, in New Zealand, in South Africa, or Egypt. I do not think it fair to impose this burden upon us."

TEA EXPORTS FROM CHINA.

Our tea-planting readers are doubtless aware that the Chinese tea season commences at the beginning of May, and is practically over by the end of December; for instance, last year out of a total export for the season of 1883-4 of 151 millions of pounds, no less than 147¼ millions were shipped before the end of the year.

This accounts in a great measure for the small effect the war between France and China has had on the London market. It is generally believed in England that long before the new teas have to be shipped in May next year, the war will be over, and there will therefore be no interruption on the shipments of next season's teas. In the meantime, the stocks in England and the exports up to the end of the year will, it is thought, suffice to meet the monthly deliveries for consumption and export of 12½ million pounds without reducing the stock alarmingly.

The recent advance of about 2d per lb. is, no doubt, owing chiefly to the improved position of the article arising from a decrease in the supply occasioned by the low prices which have been recently current for low-classed congous, and not to the Franco-Chinese war which up to this time has interfered very little with this season's export.

CHINESE YELLOW TEA.—The agent of the British and Foreign Bible Society, in describing his reception by the Chinese Governor-General of the Kuldja, wrote:—"We were offered very choice yellow tea such as the Emperor reserves for himself and his favourites, though sometimes sold by them for 50s a pound." No doubt the "yellow tea" described was composed of the finest "orange pekoe tips." Such tea could be made in Ceylon, but no one would give a paying price for it.

INDIAN TEA IN MELBOURNE.—We regret not being able to notice "shipments advised or on the water" from Calcutta. No one here has any stocks, and few dealers have hand-to-mouth supplies. It certainly seems strange that a Syndicate who so madly rushed nearly 3,000,000 lb. upon an untried market in one season should allow three months of a new season to pass with a total export to Australian ports of under 7,000 lb. Importers here seemed nervous in ordering, probably being afraid that the Syndicate would again commence shipping; the same fear may have deterred the Syndicate, and the result is all grades suitable for blenders' requirements are badly wanted, and not a single leaf is obtainable.—ALFRED HARVEY & Co., Tea Brokers.—*Australasian Trade Review.*

TEA CULTIVATION IN BENGAL.—Having recently dealt with the Report on Tea Cultivation in Assam, we now copy from the *Englishman* an abstract from the report on the culture in Bengal, including such widely different localities as Darjiling and Chittagong. There is some astounding error in the figures for average yield in all the Bengal districts. The figures 1,411 lb. per acre are as preposterously too high as 141 lb. would seem to be too low. In the case of by far the largest district, Darjiling, we are able to check the calculation, for we are told that 26,992 acres under mature plants had yielded 7,628,825 lb. This is almost exactly at the rate of 320 lb. or 4 maunds per acre, and the average for all Bengal must be considerably below instead of above this figure. It is interesting to learn, that, by manuring with cotton-seed (crushed, of course), the quality of tea had been slightly improved and the yield of leaf very considerably increased.

THE LARCENY OF COCOA.—We are informed that an ordinance is being prepared to check the larceny of cocoa which is extending to an alarming extent. On the 8th of April 1882 we discussed this important question at great length in these columns, and strongly urged the passing of some such measure as the one now proposed. The drift of the law will be to trace every pound of cocoa that is being sold, should any suspicion arise, and to enable any one to arrest any person selling cocoa pods in less quantity than three hundred pounds or cocoa beans in less quantity than twenty-five pounds, or any quantity of either without a delivery note. All dealers in cocoa shall be licensed by the Stipendiary Magistrate. It is to be hoped that the measure will, at any rate, mitigate if not check entirely, a practice which has, lately, taken such extension, as to threaten serious results throughout the cocoa districts.—*Port-of-Spain Gazette.*

HAS HELOPELTIS BEEN SEEN ON TEA IN CEYLON?—We have not, as yet, heard of any well-authenticated case of the insects being *seen and identified*, and we trust the superintendent of Abbotsford may be mistaken as to traces of their presence on tea-leaves. Several years ago insects like large mosquitoes were observed, but they turned out to be "daddy-longlegs." Last year and this, however, numbers of leaves have been noticed which correspond to the drawing in the *Tea Cyclopædia* showing spots and blotches, the result of the operations of the bug. No appreciable harm has been done to the tea. Specimens of the spotted leaves have been, at his request, sent to Dr. Trimen, and he will probably be able to settle the question as to whether the *Helopeltis Antonii*, although never seen, is present or has been.

THE INDIAN TEA INDUSTRY.—The results of the working of the Indian tea plantations for 1883, although exhibiting considerable varieties in produce and cost, are nevertheless very fairly satisfactory, and show that a steady increase in tea development may be looked for, although the competition from China, Java, and Ceylon, may involve a fall in prices. The size of the estates differs very much, varying from 7,600 acres under tea cultivation in the case of the Assam Company to the Borokai Company, which has only 850 acres. The yield of the former was 2,569,961 lb. or 339 lb. per mature acre, while that of the latter was 212,720 lb., or 265 lb. per acre. Nevertheless, though the Borokai Company had the smallest yield of all the Indian undertakings, it showed the very best results in profit per acre and dividend—viz., £9 3s 7d profit and 15 per cent. The Assam Company divided 14 per cent, although their profit per acre was only £3 8s 5d and the cost of the tea 11½d, while it sold for only 1s 1d per lb. In the case of the Borokai, the tea cost 1s, but it sold for 1s 8d, and hence the excellent dividend. Next in size of acreage to the Assam comes the Land Mortgage Bank of India, which has 6,645 acres under cultivation, though its paid-up capital (the largest of all the companies) is £308,468, while the Assam has only £187,160. The yield of the Land Mortgage Bank was comparatively low, being 1,539,120 lb. or 231 lb. per mature acre. The cost of the tea, too, was high at 1s 0¼d per lb. although the selling price was pretty good at 1s 3½d. Although things were rather against the company, which was the only one that declared no dividend. The highest capital per acre is in the case of the Scottish Assam which is £117; but the yield per acre being pretty good at £337 and the selling price 1s 4½d per lb. this company divided 5 per cent dividend. Some of the yields per acre were very large, as for instance, that of the Doom Dooma estate, where it was 617 lb. per acre, although the tea only selling at 11½d, probably from coarse plucking, the profit per acre was only £2 12s 8d and the dividend 2¾. The next largest yield was from the Borelli Company with an acreage of but 875. The yield per acre was 535 lb. the cost of making but 10¾d, the selling price 1s 2d, the result of the whole being a profit per acre of £7 17s, and a dividend of 8 per cent. The great varieties in Indian tea dividends is shown by the fact that they were—in the case of the Land Mortgage Bank, *nil*; Doom Dooma, 2¾; Indian Tea Company of Cachar, 3; Scottish Assam, 5; Jhanzie Tea Association, 5½; Dejoo, 7; Darjeeling, 7½; Borelli, 8; Lebong, 9; Jorehaut, 12½; Assam, 14; Borogai, 15. The varieties in yield are attributed principally to atmospheric and climatic causes, especially to drought prevailing in the early part of the season, which brought with it blight and a visitation of red spider. The cost of making the tea also differs very much on different estates, ranging between 10½d and 1s 1¾d, while the value per lb. varies from 11¼d to 1s 8d. It is satisfactory to observe that the taste for India tea in England is steadily on the rise, so that the planters have good reason to expect a tolerably prosperous future.—London *Times.*

FORESTRY.—As we have good reason to believe that a bill to regulate forest conservation in Ceylon will be introduced during the approaching session of Council, we quote the following notice in the *Pioneer* of a pamphlet by Dr. Brandis, the former head of the Indian Forest Department, which shows the importanee of the question:—

It seems probable that some of Mr. Cross's sudden enthusiasm on the matter of Indian forests may have been inspired by an interesting pamphlet just published by Dr. Brandis, the late head of the Forest Department in this country. This little book, which is a reprint of a paper written for the *Journal* of the Scottish Arboricultural Society, is excellently suited to popularize a subject in which most people feel a natural interest, but which few care to follow through the intricacies and technicalities of the official reports. Dr. Brandis gives us the whole story within the compass of a magazine article. He describes the gradual origin of the State system in the destruction of forests that followed on increase of agriculture and population brought about by the prosperity of the country under British Government; the present constitution of the Department and its working; the classification of forests, their botany and the values of their different products and having done this he enters into a consideration of the larger and more general questions that underlie the whole forest policy of the Government: such as the influence of forests on climate, and on soil; their effects direct—and indirect—upon the water-supply of localities; the good done to people by reserves of fuel and fodder as set against the loss that may be inflicted on them by protective restrictions. All these are obviously topics of the highest interest and importance, but the aspect of Indian forestry that most engaged Mr. Cross was naturally the financial one. On this point all that he said, it is needless to say, is fully corroborated by D. Brandis, for the plain accounts of the Department do not admit of being read in different ways according to the predisposition of the reader; but the latter has instituted a comparison with the results obtained in France and Germany that makes the bear record of Indian progress very much more instructive. In France indeed the figures of revenue and expenditure approximate with singular closeness to those of this country. The former is quoted by Dr. Brandis at £1,405,104 and the latter at £641,508, leaving a surplus of £763,596; while the Indian forest revenue during the past official year amounted to £1,040,000 and the charges to about £660,000. When we come to compare the areas of forest, however, there is a very wide difference, the French State forest covering less than 4,000, while those under the Indian Government (including the second class reserves) cover over 29,000 square miles. And Prussia which can boast of 10,000 square miles of State forest derives a net gain therefrom of nearly a million sterling annually. The comparison considered absolutely does not appear indeed particularly advantageous to ourselves, but the distinction between the cases is obvious, "In these countries," as Dr. Brandis writes:—"regular and systematic forest management has existed for several centuries, and the result may be seen in well-stocked forests with a regular gradation of ages, which yield large annual crops of timber and other forest produce. In India the first real attempt to introduce systematic forest management is barley 30 years old." The lesson of comparison is manifestly hopeful. Setting aside the difference of their products, if the 4,000 miles of French forest yield a greater return now than the 30,000 of Indian, of what vast value should the latter be when the same system of administration has been thoroughly applied to them and has had time to make the effects of its working fully felt.

CINCHONA CULTIVATION IN CEYLON.

In the Annual Report by Dr. Trimen, on the Royal Botanic Gardens in Ceylon for the year 1883, he quite confirms a statement that we quoted a few months since as to the unsatisfactory outlook for the once promising and extensive experiment in the cultivation of cinchona by private persons in that island. The interests involved may be estimated from the fact that the export from Ceylon during the last commercial year amounted to nearly seven million pounds of bark. But there has been a large decrease in the number of cinchona plants, and Dr. Trimen at the time of writing his report anticipated that the large export would not be maintained, whilst a fear is expressed that a large proportion that had been exported "was very poor stuff," which at the prices then prevailing could hardly have been worth sending home. It is estimated that at the end of the year there were probably 128,000,000 of cinchona plants in Ceylon, of which not more than 22,000,000 were over two years old, and it is thought that the proportion of the other 122,000,000 which would grow up to maturity would prove to be very small. The heavy mortality of seedlings and young trees now experienced in the island has caused much disappointment, and is said by planters to exceed that which obtained formerly. The cause of this mortality has been assumed to lie in a "degeneration" of the cinchonas since their cultivation in Ceylon, each generation being supposed to be inferior in vitality to the one that preceded it. But Dr. Trimen does not see any clear evidence of this, as, under similar conditions, the tendency to die at an early age is as marked in plants grown from seed fresh from South America or the West Indies as in those from Ceylon-grown seed. He considers the cause is to be sought rather in the climate and soil of Ceylon. Much of the shallow soil and cold subsoil and many of the wet, windy and exposed hillsides have proved very unsuitable for cinchona as a permanent cultivation; but in well-protected localities, with a deep soil and good drainage, it is thought probable the plant grows as well now as it ever did in Ceylon. But even under the favourable conditions that might be supposed to be present in the experimental plantations in the Government gardens, the experience cannot be said to be promising, for the manager at Hakgala reports that the plants were dying there at such a rate as to necessitate special replanting, and that although there had since been some improvement, hardly a plant had made satisfactory growth, whilst those of the calisaya class had nearly all died.—*Pharmaceutical Journal.*

FEEDING THE SILKWORM.

M. J. G. HAMMACK.

There are three kinds of silkworms: Annuals, Bivoltines, and Trivoltines. The Annuals produce but one brood a year, Bivoltines two broods, and Trivoltines three. After considerable experience we are satisfied that the last two breeds cannot be raised as profitably as the pure Annuals. Annuals' eggs will not hatch prematurely, but the hatching cannot be deferred for any length of time, after the trees are in leaf, except by using ice, in which case the vitality of the eggs is more or less injured. It is necessary in any climate to watch the advance of the mulberry tree in the spring.

The following are some of the terms used in silk culture:—Grain is silk-worm eggs; the cocoonery is a house where the worms are raised; moulting is the time at which the worms change their skins. Chrysalis is the form assumed by the worm inside the cocoon. Floss silk is loose silk that envelops the cocoon, and is carded and spun like cotton. The cocoon is the silken covering with which the worm surrounds itself before passing into the chrysalis state. Raw silk is silk that is reeled from cocoons. The ages are periods between two moults; green-cocoons is a name frequently applied to fresh or unchoked cocoons. Pierced cocoons are those that the moth is allowed to perforate, and are sold for waste silk. Choked cocoons are those stifled, or have the chrysalis killed, by steam or in the hot sun. Litter is the accumulation where the worms lay, of dried and partly consumed leaves, and offal of the worm themselves.

GATHERING THE LEAVES.—If the trees are desired for standards, at two years old, they may be stripped of their leaves. The leaves must not be gathered before sunrise or after sunset, when dew or fog makes them damp. They should be gathered before nine o'clock in the morning for the day's feed, and before seven o'clock in the evening for the morning's feed. If leaves are dusty, they should be wiped with a dry cloth. In case of threatened rain, leaves may be gathered two days ahead, and kept in a cool place. If it should become a necessity to gather leaves in the rain, spread them out on the floor in the shade in an airy place, or dry them by shaking in a sheet. Give to the young worms the best, tender leaves, after the second moult. After the last moult, give to the worms the thickest and best leaves the trees produce.

Silkworms should be fed during the day and night, from the hatching to the spinning time. Give them all they can eat at regular hours. Worms matured in twenty-five or thirty days will produce more silk, and of a finer quality, than those fed forty days, and the short-lived worms are less liable to disease. Worms will never leave the feeding shelves if properly fed. The worms should receive light meals, first, at six in the morning; second, at eight; third, at ten; noon, two o'clock, four, six, eight, and ten. In very warm weather an extra feed should be given at midnight. On cool days the worms will consume less food than in warm ones. The young silkworms should have one single layer of chopped leaves for their meals, and if these become dry, feed again in half an hour.—*American Agriculturist.*

FORESTRY EXHIBITION IN EDINBURGH.

(Continued from page 226.)

INDIA.—Amongst the various exhibits, perhaps the largest and most important is that contributed by our Indian possessions. These are neatly arranged in the central transept, and include very extensive collections of woods, forest products, both in a raw and finished state, implements of forestry, examples of native industry, as well as a variety of miscellaneous objects, to which we shall have occasion to refer at some length later on. The most important for present reference is known as the "Indian Collection of Timbers," sent by the Indian Government from Calcutta. This immense collection comprises about 800 specimens of timber, all of which have been cut from indigenous trees. They are not only distinctly named, but in many cases the labels contain a vast amount of information regarding the texture and durability of the timber, as well as strength, weight, and uses to which it is generally applied. Another point which deserves special notice is the arrangement of this collection, for the gum and resin producing trees are placed by themselves, and so on with those yielding tannin matter, dyes, oils, and fibres. The Padowk tree (Pterocarpus indicus), of which there are some beautiful logs, seems, from the number of uses to which it is applied, a most valuable acquisition.

The timber of this tree varies very much in colour, that from some specimens resembling very nearly our common Larch, while others can hardly be distinguished from the finest Mahogany. A beautiful and much-admired mantelpiece made of this wood is also exhibited, as well as various other articles, all of which clearly prove that this timber is admirably adapted for decorative purposes generally. Numerous sections of the invaluable Teak tree (Tectona grandis) are shown both in a rough and finished state. This wood is exported in great quantity to Britain, being found of immense value in the construction of vessels, railway carriages and waggon wheels. The beautiful carved work in which it is also used is well exemplified in the cabinets, panels, and furniture sent for exhibition.

From Burmah come some immense Bamboo canes ranging in length from 80 to over 90 feet, and said to have been the result of one season's growth. The Sisoo, another beautifully-grained wood, is in great request for carriage-wheels, and seems remarkably light and tenacious in proportion to its weight. Of resins, oils, gums, perfumery, and vegetable dyes there is also a large and varied collection, as well as native carts and waggons, articles of furniture, all of the most exquisite design, and the highest excellence of workmanship. Hunting trophies, as illustrative of the fauna of the forest, have been lent by H. R. H. the Prince of Wales, Prince Christian, the Duke of Edinburgh, &c., and arranged with great taste and set

up with artistic skill. The above magnificent collection of Indian resources has been set up by Colonel Michael, who has been appointed Director of the Indian collections, with an amount of taste and skill that is well worthy of imitation.

SINGAPORE.—From this island, a British settlement, situated at the southernmost extremity of the Malay peninsula, comes a goodly number of specimens of indigenous forest trees, chief among which are the Seriah, the Daroo, and the Ballow, a kind of Teak. The greater part of the island is well forested, the woods being composed of different kinds of trees, several of which are well adapted for house-building. The soil of the interior is composed of sand or clay ironstone, with a large percentage of vegetable matter, which gives it a very black appearance. Near the coast are some low tracts of swampy ground, on which a hard and durable tree, named the Billion, is commonly found. The Pepper tree and Betel Vine (Piper siriboa) are well cultivated, as well as different fruits, vegetables, nutmegs, rice, coffee, and cotton.

THE ISLAND OF MAURITIUS contributes a most interesting collection of fibre-producing plants, no less than 200 specimens in a rough state being shown. In addition to flowers and fruits the soil of Mauritius grows Wheat, Maize and Yams, but the principal product is sugar. None of the timber is of great size, but amongst those exhibited many appear of first-rate quality and well-adapted for general purposes. Hundreds of acres of the lowlying lands on the northern and western districts of the island, where formerly the Sugar-cane grew, are now waste and unemployed, owing partly to the effects of hurricanes, drought, and disease of the cane. To replace this land numbers of acres of the primæval forests have been cleared away, which it is believed has had an injurious effect upon the island by increasing the temperature, and, therefore, correspondingly lessening the humidity of the soil.

SIAM.—This country, long noted for the variety and abundance of its fruit trees, is also particularly rich in valuable timber trees, including the Teak, Sandal, Ebony and Rosewood. The forests, which cover nearly all the mountain ranges of the country, also yield several articles of trade, such as cardamoms, gamboge, and Aquilawood, the latter much renowned for its perfume. A very extensive and interesting collection of these native woods, numbering over 500, and all distinctly labelled, have been sent for exhibition, including, amongst others, those producing gums and resins. The most important industrial occupations are iron and tin smelting, gold beating, the making of cloth, glass and pottery.

TRANSPLANTING MACHINES.—Several transplanting machines, both on the old and improved styles, are shown. One with two wheels, similar in all respects to the Janker now in general use for transporting heavy timber, seems, from its simplicity of construction, and the great lever-power attainable, to be a machine well worthy the attention of those engaged in transplanting. Another, with four wheels, but of rather unwieldy construction, must be of great value for town or park work, where, by transplanting large trees, immediate effect is at once obtained. Trees up to 10 tons in weight can, it is said, be readily removed by this machine. The same exhibitor, Mr. James Whitton, gardener, Coltness, Wishaw—who, by-the-bye, seems to have devoted no little time to improving the machines of his fellow-craft—shows a very efficient as well as simple plan of removing shrubs, whereby the ball is preserved intact—a matter of much importance in dry weather, and where plants destitute of fibrous roots are being transferred to a distance. Messrs. John Greig & Son, engineers, Fountainbridge, Edinburgh, exhibit what is perhaps the most handy and at the same time efficient transplanter we have yet seen. The Sycamore tree shown within its frame was lifted by the machine out of Turner's nursery, and conveyed to its present position, where ample opportunity is offered for a thorough inspection of the simplicity and efficacy of this valuable machine in transplanting as well as transferring to a distance trees and shrubs of average size. —*Gardeners' Chronicle.*

EDIBLE CACTI.

The Prickly Pear or Indian Fig, as it is sometimes termed the fruit of Opuntia vulgaris, is known in our fruit shops, but there are many other species of the Cactus family which are edible, although only locally known where they are indigenous—among these are Opuntia Ficus indica, Opuntia Tuna, O. Rafinesquii, and O. occidentalis. New Mexico, Arizona, California, and Utah, are the habitats of most of these. Cereus giganteus and C. Thurberi also furnish edible fruits; the former attains a height of 25 to 50 feet, whilst C. Engelmanni is a dwarf species, with large scarlet flowers, and refreshingly cool fruits of a Strawberry taste. C. Quixo of Chili is a stately Cactus which attains a height of 15 feet. The charming snow-white flowers are followed by sweetish mucilaginous fruits available for the table. The fruits of the Opuntias are much eaten by the Indians under the common Spanish name of *tunas*, and great quantities are dried for use in the winter. The fruits of the Opuntias are of a bright red to purple colour, of a rather pleasant, sweet, somewhat acid taste, and have thin stems and rather large seeds which are discarded. They are much eaten by the Indians. The skin is studded with bunches of very fine downy spines, which they brush off with a bunch of grass. The Apache Indians use wooden tongs to gather the fruit and prevent scratching by the spines or thorns of the plant. Some tribes dry the unripe fruit of the Opuntia for future use, to be cooked with meat and other substances. The fresh unripe fruit is often boiled in water from ten to twelve hours until soft, when it becomes like Apple-sauce; then, being allowed to ferment a little, it becomes stimulating and nutritious. Some Indians roast the leaves of the Opuntia in hot ashes, and when cooked the outer skin with the thorns is easily removed, leaving a slimy, sweet succulent substance, which is eaten.

In the province of Catania, in Sicily, in Algeria and Egypt, the Opuntia Ficus indica is regularly cultivated for its fruit. The product in Egypt is about 10,000 cwt. annually. In Sicily four varieties are known—one with yellow fruit, one with white fruit, one with red fruit, and one without seeds. The two firstnamed varieties are chiefly cultivated, as they are most productive, and the fruit is sweeter and larger. These fruits can be kept during the winter up to March or April if covered with hay or paper. A hectare of ground planted with these Cacti yields a return of about £20, and the cost does not exceed £2. The fruit of Cereus giganteus is Pear-shaped, of a greenish-yellow colour, with a few small spines scattered over the surface, which fall off as the fruit becomes thoroughly ripe. The fruit is borne upon the highest part of the plant, and is usually gathered by means of long hooked sticks; the interior is of a beautiful red colour, and looks tempting. The rind is pulpy, fibrous, juicy, and sweet; the pulp is very palatable (and is full of small black seeds, which are also eaten), reminding one of Figs, the only difference being that it has more moisture. The seeds are indigestible unless when chewed. The Indians consider this one of their greatest luxuries, and as long as the fruit is obtainable care for nothing else.

To dry this fruit as a preserve the seedy pulp is placed between soft Indian Corn husks, the ends of which are tied, and it is then dried in the sun for winter use or trade. It is also put into earthen pots when fresh, secured from the air, and sold in the settlements. It retains its sweetness for a long time. A clear light brown syrup is expressed from the pulp and sold in gallon jugs. The Papajo Indians are the largest producers of this syrup. The Pimo Indians annually prepare a wine from this fruit, called by the Mexicans *tis wein*, by taking the fresh pulp or the syrup and mixing it with a certain quantity of water in earthen vessels and exposing it to the sun for some time to ferment, after which it is fit for drinking. It is of a clear amber colour, and in every respect superior to much of the wine on sale. It is highly intoxicating, with the taste and smell of sour beer, but some time elapses before its stimulating effects are felt. When the wine is ready for use, the Indians celebrate an annual drinking festival.

Cereus Thurberi is commonly called *petahaya* by the Mexicans. It grows to 18 or 20 feet high, and 4 to 6 inches in diameter, and bears two crops of fruit per year. The fruit is the size and shape of an egg, and is thickly co-

vered with long black spines; as it ripens it becomes tinged with red, and the spines fall off, the fruit splits open and exposes a rich red juicy pulp with small black seeds. The fruit is decidedly better than that of Cereus giganteus, but is used in every respect for the same domestic purposes. The Papajo Indians in transporting earthen vessels filled with syrup or fruit to market, cover their jars with a thick coating of mud, which renders them less liable to waste in handling and at the same time keeps the contents cool and prevents evaporation, the crockery used being very porous.

The fruit is eaten in enormous quantities, and being very nutritious, the consumers quickly acquire an extraordinary increase in bulk. In making wine or syrup the seeds are easily separated from the pulp by the use of water. They are carefully collected, dried, parched, and pulverised, after which process they are digestible and nutritious.

The last species to be noticed is Echinocactus Wislizeni. This singular species of Cactus is commonly called by the Spaniards *biznacha*, and, being 20 inches or more in diameter, a section of the stem is often employed as a cooking vessel. The seeds are small and black, but when parched and pulverised make good gruel and even bread. The pulp of the fruit is rather sour and not much eaten. Travellers in passing the Cactus wastes often resort to this plant to quench their thirst, its interior containing a soft, white, watery substance, of slightly acid taste, which is rather pleasant when chewed. It is a common sight to see on each side of the road these plants with a large perforation made by the thirsty traveller. An Indian when travelling and wishing to make a meal selects a large plant 3 feet or more long and 2 in diameter, cuts it down and hollows it out so as to form a trough. Into this he throws the soft portions of the pulpy substance which surrounds the central woody axis, and adds meat, roots, seeds, meal, fruits, or any edible thing on hand; water is added, and the whole mixed together. Stones are then highly heated and dropped into the mixture, and as they cool are taken out, licked clean, re-heated, and returned to the cooking vessel until the mixture is thoroughly boiled. This is a favourite dish with the Indians of Arizona. The Papajo Indians pare off the rind and thorns of large plants of this species of Cactus, letting it remain several days to bleed, when the pulp is poured down to the woody axis, cut up into suitable pieces, and boiled in syrup of the Cereus giganteus or Cereus Thurberi. If a kind of sugar which is made by the Mexicans is attainable it is employed instead of the syrup, thus forming a good preserve. These pieces when taken out of the liquid and dried are as good as candied Citron peel, which they very much resemble in taste and substance.—P. L. S.—*Gardeners' Chronicle.*

FIBRE INDUSTRIES IN INDIA.

That we are sadly deficient in directing power for the guidance of future fibre industries, there can be no sort of doubt. The trade in jute has seen great prosperity. It has grown within half-a-century from very small beginnings to huge proportions, and tens of thousands of cultivators now earn a good livelihood by the growth and preparation of this fibre. It is beyond doubt well suited to large tracts of land in Bengal, and it is an industry which the ryots take to very readily. A million of acres are now under jute cultivation in Bengal, extending throughout various parts of the presidency: and being grown for the most part within easy distance of rivers, the transport of the raw material to Calcutta is not a very difficult or costly affair the freight down usually being only eight annas a maund. When we remember how, from a small beginning in jute exports of the value of £62, in 1828, the shipments have attained to the enormous value of £8,000,000 sterling, and that a very large part of this gross amount goes to the cultivator, we see how much the grower and the owner of the soil stand indebted to thetrade. But unfortunately the fibre trade has at length fallen upon evil times. Over-production of the raw material and a diminished demand for jute bagging have reduced the value of the article in first hands by nearly one-half. The finer qualities we find stood at R5-2 in 1880, whereas they are now quoted at R3-6, and common sorts which were worth R4-2 in 1880 will now command only R2-8 the maund. Seeing that all the expenses of freight from up-country baling and other charges are much the same now as four years ago, it follows that the chief reduction is in the amount that the grower receives, so that the probability is that he finds it a difficult matter to pay rent and support his household. No doubt this state of things will throw a good deal of land under jute out of cultivation, which must siguify lack of employment for large numbers of people, and the price of the article, once depressed, cannot easily be raised to its former standard. The statistics of the current season will show to what extent we are right as regards the area under cultivation, and what we are now concerned with is the course for unemployed cultivators to adopt. In an emergency of this kind the need for some guiding influence is much felt: and it is now that the office of an agricultural association might be of the utmost value in making suggestions for the future efforts of ryots. Such a body would have it in its powre to institute comparisons as to price of the various fibrer in the markets of the world, and would be in a position to tell the landlord and the cultivators that their land and their labour might be devoted to the growth of other fibres commanding a far better value than jute. In the London market, for instance, jute in the raw state rarely realises more than £18 the ton, and it drops down occasionally as low as £5 and £6,—the ordinary price of the common kinds being £8. These figures necessarily leave a very small margin for profit after deducting all charges, and it therefore behoves those who have a care for the interests of landlord and labourer to introduce other plants, the product of which will command better figures.

The value of a fibre in the markets of the world depends largely upon the uses to which it can be applied. Jute makes excellent sacking, but is not suitable for rope-making or the better kinds of cordage, as it will not stand any strain, while there are few higher purposes to which it can be applied—at least to any great extent. In order to obtain a higher range of prices, fibres must be found capable of being employed for the finer cordage or the most powerful rope, or, on the other hand, for the manufacture of delicate and valuable fabrics. With some agency or intermediary capable of putting the matter before the native cultivator it might well be said to him: Substitute the rearing of some fibre that will pay you better, a fibre which may be grown in the same soil as jute, and which may be prepared in very nearly a similar manner. Of these there are two, the Rhea and the Marool, or Moorva, or as it is known botanically, *Sansivera Zeylanica*, from having been originally noticed in Ceylon where it grows wild over large tracts of country and where its uses are well known. This useful and prolific plant is met with in the Madras Presidency. Dr. Forbes Watson in a recent lecture at the rooms of the Society of Arts shewed some of it worked up into cordage and rope, and said that manufacturers value it at £40 a ton as it is stronger and lighter than Manilla hemp, and of a beautiful light color. It grows so freely, where it has once taken root, as to require no cultivation, and its preparation is as simple as that of jute. Here then is a fibre which is worth double the price of the best jute, and it must be evident that if some of the jute lands where put under this plant, it would relieve the Calcutta market of the excessive production of the lower-priced fibre, and would pay the grower far better for cultivation and preparation.

There is nothing connected with the growth of these two plants or the preparing of their fibres for market that give any more trouble than in the case of jute, except that the rhea requires a little more careful handling, and the weight of the proposed fibre will not be so much per acre of ground as in the case of the lower-priced article. A very little experience would suffice to enable the ryot to succeed as well with the China-grass fibre as the Chinese, who experience no difficulty with it. As regards market-value, careful preparation has much to do with the figure it brings, but there is a wide range in price between it and jute, seeing that rhea rarely sells for less than £35 and usually up to £50 and £60 the ton. In the cultivation of rhea, though much more has to be done than for the marool, which needs literally no care, it requires no more attention than is necessary for jute, the ground for which has to be ploughed up three or four times. The rhea or China grass has a tap-root which descends at least two feet into the soil, and to enable it to do this freely,

the land should be well opened; but this is the nature of cultivation required. The young plants are put from the nursery in rows eighteen inches apart, but after the first year they will, if the soil be good, very soon cumber the ground and require thinning. After a cutting out of the matured stalks, they might be relieved by removing every alternate root, which could be utilised for filling up vacancies and for extensions. If water is available it would be profitably applied during very dry weather, but only sufficient to keep the roots moist, and when the flowering of the plant comes on, no more watering should take place in order that the shoots may ripen and form the fibre properly. They are, when quite brown near the ground, cut down and taken to the retting ground, and there subjected to the same or nearly the same process as jute and hemp, *i.e.*, steeped in water until in a state to part with the outer cuticle of the stem, when the fine fibre is readily separated from the woody matter. But in order to ascertain when the proper time for scalching has arrived, a good deal of attention and care is required. For the work of separation the labor of women and children is more suitable than that of men, as the fibre though strong is extremely fine and delicate. For the process of taking off the fibre a good supply of water is needed, as for jute, and the same may be said of the preparation of the *Sanseviera* fibre. For extracting both of these fibres, the new machine patented by Death & Ellwood is said to be admirably adapted, doing the work rapidly and at a small cost.—*Indian Agriculturist.* ["Doing the work rapidly and at a small cost"? This is just the question which has to be settled. As yet the complaint is of the small outturn of clean fibre per diem.—ED.]

RUBBER GROVES.

Last year we bought $8,600,000 worth of rubber from Brazil. Next to coffee and sugar, rubber holds third place in Brazilian exports, and is in great demand in this country because of its superior quality. It is being used now in countless ways, and in late years its consumption has doubled, passing in a stride from the rank of a luxury or non-essential to that of a necessity. Since the industry of collecting the sap and preparing the crude rubber for the market is altogether in the hands of barbarous and nomadic Indians, it is not surprising to learn that no attention is paid by them to the future. They follow blindly the old methods, and the wasteful system of half a century ago is obstinately pursued without any effort towards improvement and economy. These besotted people have no thought beyond immediate profit, and in consequence millions of rubber trees have been destroyed and many others abandoned from premature and inordinate tapping. Intelligent Brazilians, who have given the matter some thought, are of the opinion that the industry has but a short time to live, unless the government interferes and introduces economic measures. When care is taken the results are highly satisfactory. It is known that if the trees are not tapped in August and September, when they change their leaves, groves have continued to yield abundantly for thirty years, and are still in good condition. Little or nothing, however, has been done to propagate the trees, and indiscriminate tapping continues as if the supply were inexhaustible. It is painful to rubber dealers to contemplate that there are no indications at present that effective precautions will be adopted to save the valuable rubber groves.—*Independent Journal.*

ANALYSIS OF THE SO-CALLED AMORPHOUS ALKALOIDS OF PERUVIAN BARK.

BY VIRGIL COBLENZ.

The author, after giving an account of the manufacture of a cheap febrifuge by the British government in India, describes three of the most prominent of these so-called amorphous alkaloids in the American market. These are sold under the names of "Dextro-quinine," "Quinquinia," and "Powdered Purified Chinoidine."

In one instance the composition is stated on the label to be 15 per cent each of quinine, quinidine, and cinchonidine; 25 per cent cinchonine, and the remaining 30 per cent amorphous alkaloids or purified chinoidine. They are all recommended as equal to quinine in the same dose, while the price at which they are offered is considerably less.

A qualitative analysis showed each of the three specimens under examination to contain about from two to five per cent of moisture, being of neutral reaction, free from non-volatile compounds, and containing all the four alkaloids enumerated above. In one specimen traces for ammonia and sulphuric acid were found.

In making a qualitative analysis some difficulty was experienced in obtaining the alkaloids free from resinous and coloring matter, which interfered with their estimation. It was thought that, as these compounds were alkaloids in some degree of purity, their solution in a weak acid, and subsequent neutralization with an alkali would yield the free alkaloids in a form sufficiently pure for estimation, but such proved not to be the case.

The method of the U. S. Pharmacopœia for assaying cinchona barks was then, in part, adopted, and gave satisfactory results. This is the familiar process of decomposing the alkaloids, exhausted with dilute hydrochloric acid, with slaked lime, and subsequently exhausting the dried and powdered precipitate with boiling alcohol, which leaves the alkaloids in a tolerably pure form upon agitation with chloroform.

For a quantitative separation of the alkaloids the method of De Vrij was followed. To the total quantity of the mixed alkaloids resulting from each assay was added a small quantity of quite finely-powdered glass, and ten times the weight of the alkaloids of stronger ether. Upon agitation with the glass the alkaloids were detached from the flask, and, being ground up by the glass, those soluble in ether readily dissolved therein. The separation of the two classes of alkaloids was thus effected, and subjected to further examination with the following result:—

NO. 1.—TWO GRAMS SAMPLE TAKEN.

Quinine	·012	or	·60 per cent.
Quinidine	·477	"	23·85 "
Cinchonine	·475	"	23·75 "
Cinchonidine	·155	"	7·75 "
Uncrystallizable alkaloid	·361	"	18·05 "
Total alkaloid; matter soluble in ether	1·480	"	74·00 "
Moisture	·040	"	2·00 "
Non-alkaloidal matter	·480	"	24·00 "
	2·000 gms.	or	100 per cent.

NO. 2.—TWO GRAMS SAMPLE TAKEN.

Quinine	·117 grams	or	5·85 per cent.
Quinidine	·259	"	" 12·95 "
Cinchonine	·287	"	" 14·35 "
Cinchonidine	·450	"	" 22·50 "
Uncrystallizable alkaloids	·362	"	" 18·10 "
Total alkaloid; matter soluble in ether	1·475	"	" 7·377 "
Moisture	·100	"	" ·500 "
Non-alkaloidal matter	·425	"	" 21·25 "
	2·000 gms.	or	100 per cent.

NO. 3.—TWO GRAMS SAMPLE TAKEN.

Quinine	·014 grams	or	70 per cent.
Quinidine	·098	"	" 4·90 "
Cinchonine	·205	"	" 10·25 "
Cinchonidine	·401	"	" 20·05 "
Uncrystallizable alkaloids	·902	"	" 45·10 "
Total alkaloid; matter soluble in ether	1·620	"	" 81·00 "
Moisture	·045	"	" 2·25 "
Non-alkaloidal matter	·335	"	" 16·75 "

ANALYSIS OF COMMERCIAL SULPHATE OF QUININE.

BY M. J. E. DE VRIJ.

M Juryfleisch has rendered a service to the readers of this journal by inserting in the April number the fine work which my compatriot and friend, M. Oudemans, published a few years ago in the *Annalen der Chemie*. On applying M. Oudeman's method to the examination of commercial sulphates of quinine, I have obtained results which I am happy to make known.

In the year 1835 I had the pleasure of making the personal acquaintance of M. Pelletier, one of the authors of the discovery of quinine, and of receiving from him a fine collection of alkaloids prepared by himself. I had thus a sample of pure quinine from an authentic source. I religiously preserved this precious souvenir for years, until my studies on the alkaloids of cinchona compelled me in 1856 to sacrifice it. I found then that even this quinine, prepared by M. Pelletier, contained traces of cinchonidine, an alkaloid discovered by M. Winckler in 1848, and consequently unknown to M. Pelletier at the time of his remarkable discovery of quinine. This cinchonidine, discovered at first by M. Winckler in one particular cinchona, exists in different species more generally than was believed.

The calisaya bark from Bolivia, employed by M. Pelletier and his contemporaries contained traces of it, a fact of which I became convinced on analyzing a sample of C. calisaya of those distant times, kept as a souvenir by one of the heads of the firm of MM. d'Ailly et fils, of Amsterdam, who at the same period as M. Pelletier also manufactured sulphate of quinine. Even the cinchona known as *Cuprea* contains traces, although generally supposed to be free from it; but the application of M. Oudemans' process to the tartrate of the alkaloids obtained and separated from this bark proved to me that it really contains appreciable traces of cinchonidine.

The fact that commercial sulphate of quinine contains traces of cinchonidine was then well known to me, but I did not suspect that the quantity was so considerable. It is only within the last few months that I have been able to prove that all the commercial sulphates of quinine of France, England, Germany, and Holland which I have analyzed contain sulphate of cinchonidine in quantity varying from 5 to 18 per cent. The presence of this salt, within the limits mentioned, does not constitute an adulteration, but is a natural consequence of the presence of cinchonidine in the barks employed in the actual manufacture of sulphate of quinine.

The skilful and conscientious manufacturer can keep the presence of sulphate of cinchonidine within certain limits; but, although he can prepare the acid sulphate of quinine chemically pure, it is impossible for him to prepare commercially-pure ordinary sulphate of quinine (basic). And even if he could, he would not, because his chemically-pure basic sulphate would not be accepted by the trade which demands a slight sulphate. Now, chemically-pure sulphate of quinine is not light, but relatively heavy, as can be easily seen by dissolving the bisulphate (monobasic sulphate) in 40 parts of boiling water and saturating this solution with caustic soda. On the cooling of the liquid neutral to litmus paper, the basic sulphate will separate in beautiful silky crystals, much heavier than the crystals of commercial sulphate.

When 5 grams of commercial sulphate of quinine are dissolved in 200 grams of boiling water, and to this are added 5 grams of Rochelle salts, also dissolved in very little boiling water, the solution remains clear for a short time; and on cooling regular crystals are seen to form. After twenty-four hours the crystals should be carefully collected on a filter, washed with the smallest possible quantity of water, and dried in the air. On treating in the same manner different samples of commercial quinine, it will be found that the weights of tartrate are not identical, because the quantity of these tartrates is influenced by the water of crystallization and by the presence of cinchonine, the tartrate of which does not separate under these conditions, but remains in solution. Consequently, the weight of the tartrates obtained is one of the indications of the commercial value of the sulphate of quinine. On treating several samples in this manner I have been able to obtain quantities of tartrates varying from 88·84 to 93·14 per cent of the sulphate employed. After having determined the weight of tartrates obtained from different samples, I have submitted these tartrates to an optical examination, according to M. Ondemans' method. The result proved that the quantity of sulphate of cinchonidine contained in commercial sulphate of quinine varies from 5·47 to 18·46 per cent.

If this process is applied to different brands of sulphate of quinine, it will be found that the difference in price, from 15 to 30 francs per kilo, has often no foundation but prejudice.—*Journal de Pharmacie et de Chimie.*

FALSE JAPANESE ISINGLASS.

The following is taken from Prof. Dymock's work, "The Vegetable Materia Medica of Western India":—

History, Uses, etc.—This substance, called Yang-tsai by the Chinese and known in Europe as Mousse de Chine and *Japanese Isinglass*, is a regular article of commerce in Bombay, where it is valued on account of its supposed strengthening properties. Hanbury gives the following account of it:—"Under the incorrect name of Japanese isinglass there has been lately imported into London from Japan a quantity of a substance having the form of compressed, irregularly four-sided sticks, apparently composed of shriveled, semi-transparant yellowish-white membranes. They are eleven inches long, by from one to one-half inches broad, full of cavities; very light (each weighing about three drachms), rather flexible but easily broken, and devoid of taste or smell. Treated with cold water, a stick increases greatly in volume, becoming a quadrangular, spongy bar with somewhat concave sides one and a half inches wide." The term Chinai-ghas is loosely applied in Bombay to three substances, namely, Japanese isinglass, edible birds' nests and Ceylon moss.

Note.—This substance has attracted considerable attention in France. It was exhibited at the Paris Exposition of 1878 under the name of *Thao*. The following particulars from the catalogue may prove interesting:—Various trials have been made with it in France since 1874, especially by MM. D. Gantillon & Co., at Lyons, and the Industrial Society at Rouen. The thao is prepared for use in the following way:—After having been soaked in cold water for about twelve hours, it is boiled for a quarter of an hour, during which it absorbs about one hundred times its weight of water. If allowed to cool it becomes a jelly, but if passed through a sieve and stirred until cold it remains fluid, and in this state is more easily employed than when hot. The yellowish matter which some specimens contain can be removed by boiling for some time, when it forms an insoluble scum, which appears to consist of very thin fibres, and which remain attached to the sides of the vessel. A singular property, and one which perhaps might be turned to valuable account, is that thao jelley does not decompose solution of permanganate of potassium even when left in contact with it for twenty-four hours.

According to M. Heilmann, of Rouen, thao produces, in the proportion of one part to one hundred of water, a dressing which is supple and strong, and which gives substance rather than stiffness to calico, while dextrine, like starch, makes the tissue drier and harder, and gives less facing to the thread. The addition of glycerine gives a dressing still more flexible and soft, and while rendering the tissues less stiff, it communicates more body to them.

The addition of talc gives still greater smoothness. Once dissolved, according to M. Gantillon, thao will mix while hot with any gum, starch, dextrine or gelatine. The principal advantage of thao in dressing silk fabrics is that while preserving their suppleness, it gives them greater glossiness and makes them soft to the touch. The mixture of thao with gum tragacanth is said to be the best method of using it. Thao should, however, be used alone for materials which it is not necessary should be stiffened. As thao is only soluble at a high temperature, a moist atmosphere, fog or even rain does not affect the material dressed with it. It combines well with sulphate of copper and the chlorides of aniline and potassium, and can be used in double dyeing. It also answers well for sizing paper, &c. The only obstacle to its extensive use is its high price. There is, however, no reason why a similar substance should not be made from our common native seeweeds, of which Gelidium carneum

and Gracilaria confervoides approach most nearly in character the algæ, from which thao is made. Gelose, of which thao consists, differs from the carragheenin obtained from Chondrus crispus in its power of combining with a very large quantity of water to form a jelly. It yields ten times as much jelly as an equal weight of isinglass. For purposes of food, thao jelly is not quite so pleasant as animal jelly, as its does not melt in the mouth; it also contains no nitrogen. A great advantage which it possesses is that it is but little prone to undergo change, so much so that the jelly is sometimes imported from Singapore, sweetened, flavored and ready for use, and may in this state be kept for years without deterioration. The west coast of Australia also yields a seaweed possessing similar properties.—*Independent Journal.*

AGRICULTURE AND ITS PROSPECTS IN THE NORTH OF QUEENSLAND.

[BY THE *Queenslander's* AGRICULTURAL REPORTER.]

(*Continued from page 196.*)

In my last I contented myself with giving the general features and some of the leading charcteristics of the soil, climate, and general surroundings of the Johnstone River. In this I will enter into some of the details in connection with the sugar industry there. There are three large plantations on the river, two of which are in full swing with mills and machinery ready for crushing as soon as the cane is ripe, and on the third powerful machinery is being erected, and it is expected to be complete in time for crushing the cane crop this season. A fourth plantation, the one mentioned in my last, is not so forward; still there are plots of cane growing on different selectious belonging to this estate which may either be cut and punted to the most convenient mill, or used as plant cane in extending operations. It is worthy of notice, as illustrating one of the pioneer difficulties connected with sugar growing on this river, that on two adjoining selections on the north bank of the north branch of the river two cottages have been erected for the accommodation of bailiffs, and around one there is a cleared plot of a few acres planted with cane. The other is very near this clearing but also quite close to the scrub. * * *

On the Dalton selection I saw over 32 acres of cane, the planting of which was started in October and finished in December. This patch was remarkably healthy and vigorous, and a sight of such cane would rejoice the hearts of cane-planters in the cooler and drier South. My visit was in the middle of April, and at that time the cane stood fully 8 ft. or 9 ft. high, and was growing most vigorously. The moisture in the soil was then all that could be wished, and smart showers were of frequent occurrence, and are usually so the year through, so that failure through drought is a casualty that does not enter into the calculations of the Johnstone River sugar-planters. * * * * * * *

Another selection called Sundown had also something to show in the way of sugar. A crop of cane was cut from it last season which yielded from 70 to 80 tons per acre, all of the one season's growth. It does not answer to let cane stand over in these northern latitudes, and it will be seen, therefore, that no other district has shown greater, if even equal, capacity for producing heavy crops of cane than this, for the 80 and 90 tons to the acre spoken of on the Tweed at times has been the growth of two seasons or stand-over cane. I saw six months' ratoon cane on this selection from 10 ft. to 12 ft. high, and some older cane was as much as 14 ft. long fit for the mill, and stout at that. The Meera and the Rose Bamboo, or Rappoe, are stout canes here compared with the same in the South, and these two canes, the latter especially, are in great favour with planters everywhere in the North. On this Sundown cultivation I saw some of the largest bunches and also the largest fruit of the famous Cavendish banana I ever set eyes on, and they were grown with little or no cultivation whatever. Holes were made in the roughest and readiest manner possible for planting the suckers, and all the attention they received afterwards was an occasional surface hoeing to prevent grass and weeds smothering them. Some of the bunches I saw would very nearly fill a flour-sack—that is, a flour bushel bag; and yet I did not judge the bunches to contain over twenty dozen each. Bananas such as these are very rarely to be seen in any of the fruit shops of the metropolis, and if a bunch such as those mentioned was to be hung up it would attract a crowd This Johnstone River country might justly be called "banana land," for in the first place the banana is indigenous there; and no other part of Queensland is so well adapted for its profitable cultivation. The papaw and the mango thrive almost as well, and, as for pumpkins, they may be seen on the river bank where any clearing has been done right down to the water's edge, and even below high-water mark; and, although they are hoed and hacked about and variously mangled and despised, they are as tenacious of life as the proverbial cat, and are to all appearance there hardy perennials, and not, as they are understood to be in cooler countries, annuals. These, with sweet potatoes, yams, and taro, would yield immense supplies of wholesome food at all seasons for black labourers, and be of great service to all.

As I am still commenting on portions of Parbury, Lamb, and Raff's estate, I will mention here what I omitted to say in my last, that forty-four kanakas, five Chinese, five Sinhalese, and twenty Europeans were at the time of my visit working there, but some of the Europeans had received marching orders, and other changes were imminent. The saw-mill at work there employed a number of hands in the bush felling, and on a tramway three-quarters of a mile long hauling; also at the mill cutting; and these formed a large portion of the workers on the estate. * * * * * * *

I was very forcibly struck with the suitability of these lands for the growth of many valuable fruits, and probably in the entire range of Australian territory no locality more favourable for the growth of the tea plant will be found than here. When it is remembered that tea requires a fertile soil and a humid climate to flush sufficiently to be remunerative, it will be seen that these essentials are here in perfection, and tea is one of the possible, if not probable, products of the Johnstone River region. Coffee is also destined to luxuriate and be successfully cultivated here. Not on the low lands though; the hillsides of this scrub country are exactly the thing for coffee, and will produce it of very superior flavour and value to the rich alluvial flats. I heard that a coffee planter of experience had located himself there with the intention of prosecuting the industry, and I am certain that in good hands it will prove remunerative. That the cultivation of the coffee plant will eventually succeed cannot be doubted, seeing that it has already been grown experimentally in all the coast country of Queensland.

FRUIT-GROWING IN QUEENSLAND AND ITS TROUBLES.

Visitors to Queensland from the other colonies—and indeed, from more distant lands as well—often express much surprise that the quantity of fruit produced here is so limited. Most of the tropical fruits can be grown with little difficulty, and, in moderately favourable seasons, abundant crops of full-sized and well-flavoured fruit are produced. But, in addition to these, many of the fruits of the colder climates can be cultivated with success. We are, therefore, very advantageously circumstanced in some respects, but, instead of supplying all the would-be purchasers of fruit within the boundaries of the colony, and having large quantities to export, we are really dependent to a large extent upon our neighbours for many of the fruits which grow here with very little attention. Then, too, in the matter of preserves, almost the whole of the many thousand pounds' weight that are annually consumed are imported from Victoria, Tasmania, South Australia, America, and elsewhere. It is not a very great while since an enterprising gentleman determined upon starting a jam factory near Rockhampton. Fruits of excellent quality are grown in that neighbourhood, and the local market is a good one, so that, on the whole, his prospects of success seemed to be fairly good. But the attempt ended in failure, and it arose from a cause which, at first sight at any rate, might be considered one easy of remedy, if the farmers and settlers

care that the industry should be permanently established; it failed because of the inadequate supply of fruit.

It is not surprising that persons who are unacquainted with the difficulties which have to be contended against should think slightingly of our settlers for allowing others to supply in this way what can be produced here so easily, but as greater knowledge of the subject is gained this feeling becomes much weaker. There is no great trouble in getting the trees to bear, but there are few countries under the sun where the obstacles to gathering the crop in good condition are so great. The enemies that a gardener in Queens and has to do battle with are numerous and persistent, and many a man who has entered the lists against them has given up the struggle in despair. No sooner is he rid of one nuisance than another presents itself, and if he retires to rest at night—after a hard day's toil in the endeavour to protect and improve his crop—a fresh set of marauders come silently into his orchard and rob him while he sleeps. They are not fanciful troubles which beset his path—they are real and they are grievous—nor are they to be despised because at first sight they seem small. Amongst nocturnal depredators, flying foxes occupy a prominent place. For months there may be scarcely a sign of them, and the settler begins to take hope; but some evening, when he emerges suddenly from his house, there is a rustling amongst the leaves, and a heavy flutter, as the leathery-winged fox hurries off to a safe distance. In a very short time the neighbourhood is swarming with these destructive visitors, and their numbers are so enormous, and their migratory habits so uncertain, that the probability of exterminating them appears to be most remote. Various methods for frightening them away from the trees have been suggested, and it is reasonable to expect that some effective plan will be found, though hitherto none of the attempts, so far as we are aware, have been attended with very marked success. But there are many other smaller enemies, whose attacks are not less persistent. There are moths and other insects which come by hundreds and thousands; but whence they come and whither they go who can tell? There is the common banana moth, which may be caught at night by hanging a bunch of ripe fruit on the veranda, or other convenient place to which they have free access. Then there is the large and beautifully-marked moth which attacks the orange when the fruit is turning colour, or even at an earlier stage. A smaller one settles on the ripening bunches of grapes, and drives its sharp sucker into the fruit, so that in a few days—even if the insects are not particularly numerous—the untouched fruit is destroyed by contact with the fermenting juice of that which has been perforated. There are other moths besides these, and, in addition to them, are the insects whose larvæ are the disgusting maggots which fill with corruption the most luscious peaches, apricots, plums, guavas, and other kinds of fruit. Strangers to the country may wonder that settlers do not grow more fruit, but those who have gained their experience from attempting to do so have quite another tale to tell, for there is scarcely one which is not liable to the attack of some sort of insect abomination. After all, then, there is an explanation which must be accepted as one of much force. It, at any rate, enables us to understand how it is that many a stout-hearted man who has attempted to make fruit-growing a remunerative industry has, after a few disappointing years, turned his attention to some other enterprise; and it is important to ascertain whether these numerous and persistent enemies cannot be so reduced in number that their attacks may be kept within reasonable bounds, so that the industry may be carried on with a fair prospect of success. This, we believe, may be accomplished if it is dealt with in an intelligent manner. One of the first things to be ascertained is the source from which the insect pests are derived. The orange moth, for instance (whether it has been introduced or is indigenous to the country matters nothing), is a perfect insect, the larvæ of which feed upon one or more indigenous plants. If oranges are planted in new ground many miles away from any others, and hidden as it were in the obscurity of the bush, when they begin to bear the enemy soon makes his appearance and commences his work of destruction. It should be the object of those who are interested in orangeries to discover the plant on which the caterpillar feeds, and to distinguish the insect in this early stage of development. The moths may be killed at night in large numbers, and in the day too, for they settle in darkly-shaded bushes, and when disturbed fly for only a short distance; but having reached the perfect state they begin to be mischievous, and if possible they should be destroyed in the earlier forms, before they have time to do harm. Many of the larvæ of noxious insects feed upon plants which grow in the form of weeds on neglected ground. A large proportion of them, when about to change from larva to pupa—that is, from caterpillar to chrysalis—bury themselves a few inches below the surface of the soil; and this is a hint for cultivators whose own observation has not discovered so much for them. With these the remedy lies very much in their own hands. By keeping down the weeds the food of the larvæ is destroyed; by disturbing the surface of the soil the pupæ may be also destroyed; and these facts point a moral which it would be well to remember: "Nothing pays a farmer so well as good cultivation." If success is to be attained by those who engage in fruit-growing, it cannot be had by carelessness and negligence. The best quality in fruit is the result of good culture. Destroy all weeds; keep the surface of the soil loose by constant stirring; and destroy all immature fruit as soon as it falls to the ground. If you have pigs they will do the work well—and do it at once. Fowls may serve the same purpose—if you have enough of them—but see that the fruit is not left for more than forty-eight hours; and, if you have no animals to consume it, burn it at once. Do not bury it, for that does not destroy the insects it contains, but rather protects them. Plant only so much land as you can keep in good order. Let no weeds of any kind grow within the orchard fences, and let the land in the adjoining fields be grazed close at all times of the year, even if the stock have to be fed in the winter months. Rather let a neighbour's cows eat down the grass, without making a charge, than let it stand through the summer. By these means the plague of insects will not be exterminated, but they will be kept within bounds, and labour will have a reasonable prospect of success.—*Queenslander.*

THE FOOD OF ANIMALS IN INDIA.

Recent experience of preventable loss of life in India amongst animals both in peace and war, has not been thrown away. In 1865, the Madras Government appointed a Veterinary Surgeon to investigate an extensive outbreak of cattle disease in the Nilgiri district; and Mr. Thacker, the officer then named, continued up to 1871, in the execution of the duty then imposed upon him with the most satisfactory results. In 1873, there was a severe outbreak of murrain in the Chingleput district, and for the next three years a Veterinary Surgeon was again employed in alleviating sickness amongst animals. From 1876 to 1882, there was an absence of activity, but in August of that year a Cattle Disease Prevention Department was formed. More recently, instructions have been issued to the village officials, by the Collectors of each District, whereby reports and monthly statistics of cattle disease will in future be submitted to Government. Directly on the occurrence of an outbreak, a report is to be sent to the Collector, and weekly bulletins will be forwarded until the disease subsides. Nor have the Military authorities been inactive. A Transport Department has been organised, as one result of the lessons taught by the waste of animal life during the Afghan campaigns of 1879-81; various rules and regulations have been issued for guidance; classes for instruction in transport duties have been formed; and in future, preference will be given for employment in the Department during war, to officers who have passed through the prescribed course. All this is calculated to be of advantage in the saving of animal life. A great deal, however, has yet to be done, before a smattering of veterinary knowledge shall be general amongst military officers; and yet more ere the public is to some extent instructed. And it is because intelligent interest in this important subject is likely to be awakened, and sustained, that we periodically welcome the appearance of the *Quarterly Journal of Veterinary Science in India*, an adventure lately embarked upon by three members of the Army Veterinary Department, two of whom are serving in this Presidency.

The last number of the *Journal*, published this month,

contains an editorial on the food and feeding of animals in India, which contains much information of general utility. "It is rare," we are told, "to find any kind of grass seed prejudicial to animal health, except as the result of ergot, mould, or other fungal growth on it; but it must be remembered that all mouldy food is unsuited for animals, and its ingestion may be followed by acute poisoning, paralysis, or enterites." The grain foods on which animals depend for concentrated nutriment consist of the seeds of various kinds of grasses, the true grains, such as rice, barley, wheat, cholum, raggy, etc., and of various forms of pulse, such as chenna, coolthee, dhall, etc. Paddy has been found in India a valuable substitute for the more highly nitrogenised grains, although unhusked rice, dhall, has caused dysentery amongst the bullocks in Afghanistan. Barley and wheat are considered dangerous food for horses in England, but in India the former is sometimes, and the latter frequently, used without ill effects. The celebrated Beluchi mares are fed on cholum. Indian corn is suited for a hot weather grain. Oats are extensively given in Tirhoot to get horses into condition. Chenna and coolthee are highly valuable, but dhall has been known to cause sickness. Mote was tried at one station in the Bombay Presidency, and produced a disorder of the lungs, very like "broken wind." The golden rule to remember is, that "given an unknown food for animals, it may be freely used if a grass seed, only after careful trial of a pulse; also that light may be thrown on the enquiry by evidence as to whether natives use the substance as a food either for themselves, or for their live stock."

Next in importance to the choice of food, is its proper preparation. Some grains remain undigested, or cause grave disorders, if not properly prepared. Coolthee, oomel, and moong should be boiled before being given to horses; oxen will not digest them after being simply soaked, but camels will. Bajree and mote are best given mixed, and in an unprepared state. The water in which coolthee has been boiled is highly nutritious for animals. Chenna is best given crushed, but horses can eat it after it has been simply soaked. For debilitated horses, chenna roasted and finely powdered, or "in the form of adawar, which consists of equal parts of parched and well-ground gram and barley," is useful; or a mixture of rice and dal may be given. For cases of costiveness bran may be substituted for part of the grain; or for diarrhœa powdered rice. Suttoo, made of finely powdered parched gram and barley, is the usual India substitute for gruel. Conjee is an appetiser, and a good vehicle for medicine; and bazaar bran may be advantageously given instead of gram throughout the hot weather to horses suffering from disordered liver. Salt or mailahs should be given with the grain food as a good digestive and tonic. The latter are much affected by natives for horses or camels as a preventive to skin disease. Artificial foods may generally be divided into two classes, those containing nutritive matter, and those which are all stimulants and spices, and are useless unless given with large quantities of the ordinary feeding materials. Thorley's "Food for Cattle" is an example of the latter. The compressed food recently experimented with by Government has the drawback of not containing enough of nutritious or stimulating matter. Horse biscuits are a form of compressed food adapted to the requirements of cavalry on service, as they are very nutritious, a number of them can be carried, attached by a cord to the saddle. The Russians have made great use of them in their Turkish and Central Asian raids. Their cakes consists of ground oats and pea meal mixed with hemp seed oil, and some salt. They are baked as thin biscuits, four inches in diameter, and perforated in numerous places to facilitate soaking. They can be given either soaked or dry, and are said to keep horses in good working condition. Flesh was introduced into these biscuits by French veterinarians during the siege of Paris, and kept horses in good condition. "The Arabs and Beluchis ordinarily feed their animals on boiled sheep's head." Australian wheat chaff was recently experimented with at Poona and was found to be nutritious. "Generally the residue, after expression of oil for various economic purposes, is utilised as a feeding cake for cattle in the districts." Singili seed residue is usually procurable in this country, cattle eat it freely, and it is especially valuable for milch cows. Horses will eat the cake. Poonacs (cocoanut cake), pootoo (shell of the pigeon pea), and tour (rice bran) are all given to milch cows in various parts of this Presidency, but have not as yet been tried for horses. Ghee, jaggery, and sugar-cane are all useful for fattening horses. Sugar-cane is liked by all animals, and is an excellent change and a fattening diet. Root crops are of less value in this country than at home; but where procurable, carrots, moolees (country radishes), potatoes, and a few others can be used with benefit.

Fodder naturally divides itself into green and dry. Lucerne, guinea grass, reana, and impy are are calculated to keep the liver and skin in good order, and may be used with other fodders to tempt the appetite. Ensilage will probably permit of these grasses being preserved for use in the hot weather; but at present it has not been sufficiently experimented with. With regard to artificial increase in cultivable land, the introduction of the Australian salt bush promises to render some tracts, at present spoilt by the amount of salt in the soil, available for cultivation, and it is a valuable food for sheep. Much increase in the fertility of the soil is also secured by care in the lavish use of water, and in the construction of canals. The growth of eucalyptus reduces the moisture in swampy places and lessens malaria. Trees are an important factor in increasing the value of the return from the soil. Their leaves also form, during the hot weather, almost the sole food of such animals as camels and elephants. "Green grass, of various kinds, but especially the valuable dhoob, must always continue to be the staple article of fodder for (troop) horses in India, and it contributes a useful source of supply in most tropical countries where the grass must take refuge from the excessive heat of the sun under the surface of the ground." The sowars of the Bengal cavalry subject their horses to a course of green food (kasseil) during the hot weather, a practice said to result in abdominal complaints. Camels are also fed on kasseil. The attention of Government has recently been directed to fodder reserves. In some cantonments waste lands have been taken up and preserved from the tracks of foot passengers, carts, etc. Under exceptional circumstances, when the supplies thus yielded are not all required, they can be utilised for hay-making or seed-producing purposes.—*Madras Mail.*

ASAFŒTIDA.

BY R. W. C. PIERCE.

The name asafœtida is derived from the Arabic "asa," healing, or "isa," remedy, and the Latin "fœtidus," fetid. The botanical source of asafœtida is now generally attributed to two large umbelliferous plants, *Ferula narthex*, the *Narthex asafœtida* of Falconer, and *Ferula scorodosma*, or the *Scorodosma fœtidum* of Bunge. *Ferula narthex* was discovered by Dr. Falconer in 1838 on the northern slopes of the mountains dividing Kashmir from Western Thibet, seeds of which he sent to the Edinburgh Botanic Gardens, where they germinated and produced a plant which flourished for several years, but died after flowering. Plants more or less allied, and also said to afford asafœtida, have been met with in Herat and Afghanistan. *Ferula scorodosma* was collected in 1841 by Lehmann on the east side of the sea of Aral, and also in Bucharia. It probably extends over a wide district of Turkestan, Northern Afghanistan and Eastern Persia. Whether this plant is the *Ferula asafœtida* of Linnæus cannot be certainly decided. There is no doubt that the drug is afforded by other allied species of *Ferula* besides the two previously mentioned. The *Ferula asafœtida* of Bunge, now called *Ferula alliacea*, yields asafœtida, which is known in the Bombay market as "Hing" at the present day. Asafœtida is, according to Flückiger and Hanbury, the produce entirely of Afghanistan, but, according to Dr. Dymock, it is also produced in the province of Laristan, in Persia. The drug is forwarded to Bombay principally by way of the Persian Gulf. The asafœtida which comes from Southern Persia is supposed to be derived from *Ferula scorodosma*, and that from Afghanistan is supposed to come from *Ferula narthex*. This latter plant, however, has never been found by anyone except Falconer for certain, and by him only in Thibet, hence the botanical source of the Afghanistan asafœtida is merely conjectural. The consumption of asafœtida in Europe, America and other places is small in comparison with the amount used in Persia and India, where it is known as "Hingra." Asafœtida was known to the Arabians and Persians of the middle ages, who mention two kinds, one good, or sweet,

the other fetid. In the 13th century the Meddygon Maddfai, or physicians of Maddfai, considered it as one of the substances which every physician ought to know and use. It constitutes a favourite seasoning for food with the inhabitants of many parts of the East. The Indian Banians, who never eat animal food, use it in almost all their dishes and before their meals; even rub their mouths with it in order to stimulate their appetite. It is sometimes used by our own cooks, but in very minute quantity, in place of garlic. In many parts of Arabia and Persia it is much esteemed as a remedy for various internal diseases and as an external application to wounds. With us it is considered a powerful medicine in several disorders. It has been applied with success in the cure of whooping cough and worms, and in flatulent colics. The part of the plant from which the drug is obtained is the root, in which, after it is four years old, incisions are made. The upper part of the root, which is sometimes as thick as a man's leg rises somewhat above the surface of the ground. When cut, the asafœtida exudes in the form of a white thick juice like cream, which, from exposure to the air becomes at last of a dark brown colour. It is very apt to run to putrefaction, and hence those who collect it carefully defend it from the sun. The fresh juice has an excessively strong smell; a single drachm of it is said to smell more than a hundred pounds of the dry asafœtida brought to us. The harvest commences when the leaves begin to decay, and the whole gathering is performed by the inhabitants of the place by four different journeys to the mountains. The quantity yielded by a root varies from half an ounce to two pounds. The product got from the first cutting, which is thinner, more milky and less esteemed than that obtained afterwards, is not sold in its natural state, but is mixed with soft earth, which is added to the extent of an equal, or even double, weight of the gum resin, according to the softness of the latter. It is stated that a single ship is exclusively devoted to transporting the bulk of the drug to ports in the Persian Gulf, and that when smaller parcels are carried it is usual to tie them to the top of the mast.

As found in the shops asafœtida is in irregular masses, softish when not long exposed, of a yellowish or reddish-brown colour, externally exhibiting when broken an irregular whitish, somewhat shining surface, which soon becomes red on exposure and ultimately passes into a dull yellowish brown. This change of colour is characteristic of asafœtida, and is ascribed to the influence of air and light upon its resinous ingredient. The masses appear as if composed of distinct portions agglutinated together, sometimes of white, almost pearly tears embedded in a darker, softer and more fetid paste. It is rarely met with in separate tears, which are roundish flattened, oval or of irregular shape, from the size of a pea to that of a large almond or larger, yellowish or brownish externally and white within, and not unlike ammoniac tears, for which they might be mistaken except for their odour, which, however, is weaker than that of the masses, to which latter they are considered inferior. A very fine variety of asafœtida is said to be obtained from the leaf-bud in the centre of the root. It is known in the Indian bazaars as kandahari hing, but it is not found in European commerce. It occurs in moist flaky pieces and tears, yielding a reddish-yellow oil on pressure and mostly mixed with the remains of leaf-buds. Asafœtida has a powerful but not purely alliaceous odour and a bitter acrid and durable taste. It becomes harder and more brittle by keeping and also diminishes in smell and taste. It softens by heat without melting, and is difficult to powder. According to Berzelius its specific gravity is 1·327. I have taken the specific gravity of two specimens, one being 1·2 and the other, which we shall see further on, contains a very large amount of adulteration, being 1·7. It is inflammable, burning with a clear lively flame. It yields all its virtues to alcohol and forms a clear tincture which becomes milky on the addition of water. It forms a whitish or pinkish-white emulsion with water. When rubbed up with sulphuric acid in a mortar, then diluted and the solution neutralized by ammonia, the then slightly coloured solution exhibits a bluish fluorescence, which is due to the presence of umbelliferone. Touched with nitric acid, specific gravity 1·2, the tear becomes of an evanescent green colour. The asafœtida of commerce has been shown to be always more or less impure. The common impurities are stones, sand, powdered gypsum and wheat or barley flour, mixed in varying proportions according to the consistence of the gum resin. At Bombay it is further adulterated, frequently by opening the packages and mixing it with gum arabic.

Asafœtida consists of resin, gum and essential oil in varying proportions. The proportion of oil varies from 3 to 9 per cent the gum from 26 to 32 per cent, and the resin from 47·2 to 65 per cent. The resin is almost entirely soluble in alcohol, ether, and chloroform; it dissolves without decomposition in warm concentrated nitric acid. It contains a little ferulaic acid. Fused with caustic potash it yields resorcin, and by distillation oils of a green, violet or red tint, besides about ½ per cent of umbelliferone, $C_9H_9O_3$. The mucilaginous matter of asafœtida consists of a gum soluble in water and an insoluble portion which is bassorin. The volatile oil has a light yellow colour, with a very repulsive odour. It is at first neutral, but on exposure becomes acid and acquires a different odour. It contains from 20 to 25 per cent of sulphur, and on being distilled evolves sulphuretted hydrogen.

"Hing," the medicinal asafœtida of the natives of India, obtained from *Ferula alliacea*, consists of 37·50 resin and essential oil, 23·75 of gum. It may be distinguished from commercial asafœtida by not yielding a fluorescent solution, by its tincture not being precipitated by acetate of lead and by containing slices of roots, stem remains only being found in ordinary asafœtida, whilst the alcoholic tincture of the latter is precipitated by acetate of lead.

In the British Pharmacopœia the test for asafœtida is that it dissolves almost entirely in rectified spirit. As there is from 26 to 32 per cent of gum this cannot be true, without taking into account impurities which are always present. According to the United States Pharmacopœia it is partly soluble in ether, and at least 60 per cent of it should dissolve in alcohol of specific gravity ·820, containing 91 per cent by weight of C_2H_5HO. The German Pharmacopœia gives the following characters:—

"It gives a yellow colour with caustic soda. Does not strongly effervesce with hydrochloric acid, and is not coloured by contact with the acid for six hours. It should not leave more than 10 per cent of ash." I have worked a little upon these tests with the following results:—

No. 1. Tear asafœtida yielded 5 per cent of ash and yielded 56 per cent to s. v. r.

No. 2. Lump asafœtida yielded 56 per cent of ash and yielded 26 per cent to s. v. r.

No. 3. Lump asafœtida, specific gravity 1·77, yielded 56 per cent ash and yielded 26 per cent to s. v. r.

No. 4. "Strained" asafœtida yielded 25 per cent ash and yielded 50 per cent to s v. r.

No. 5. Lump asafœtida, specific gravity 1·2, yielded 12 per cent ash and yielded 54 per cent to s. v. r.

They all gave the NaHO reaction and the fluorescence, but they were all coloured of a greenish blue by HCl almost immediately. Nos. 3 and 4 are very impure, heavy, and have a sandy appearance.

The samples were obtained from different wholesale and retail houses, and from the Society's Museum.

Some years ago Professor Maisch, of Philadelphia, published the result of his analyses of several samples of asafœtida taken by the drug inspector of the port from different cases and from different parts of the mass. It was as follows:—

	1.	2.	3.	4.	5.
Total resin and volatile oil	36·48	43·89	62·93	39·48	30·08
Impurities...	57·50	44·01	15·20	51·70	62·09
Gum moisture and loss ...	6·02	12·10	21·87	8·82	7·83
	100	100	100	100	100

These were samples of amygdaloid asafœtida which a year previously were rejected by the purchaser as adulterated, he claiming that good asafœtida should be entirely free from sulphate of lime. The impurities in the above instance consisted of gypsum and vegetable fragments, as always met with in the resinous matter agglutinating the tears.

Dr. Dymock, in his 'Materia Medica,' states that asafœtida of an ordinary commercial quality in tears yields at least 7 per cent residue to petroleum ether, lump at least 5 per cent. and that the volatile constituents should not be less than 5 per cent in tear or 3 per cent in lump asafœtida.

In the French Codex a "purified asafœtida" is included, and which is directed to be prepared as follows:—

Dissolve the gum resin with heat in a sufficient quantity

of 60 per cent (by volume) alcohol, strain and press, drive away the alcohol by evaporation over a water-bath until the product is sufficiently thick, that when a few drops are thrown into cold water they have enough consistence to work up between the fingers without adhering to them. —*Pharmaceutical Journal.*

The sugar-planters of New South Wales and Queensland (says the Melbourne *Argus*) should make a note of the following paragraph from a New York paper:—"A new industry promises to be highly productive in the south. It has been discovered that steam-blown cane can be manufactured into paper-pulp by merely beating up the blown fibre in water, in an ordinary beating or rag-engine, without boiling or chemicals. This is quite important, as the South is extremely rich in cane. There are hundreds of square miles there covered with *Arundinaria macrosperma*. This, after being cut, matures again in three years, affording a new crop. This pulp and the cane-fibre may be used in many manufactures. The pulp can be employed in the production of almost every article for which *papier mâché* is employed at present. Works are already in progress at Wilmington and Norfolk."—*Queenslander.*

On another page (363) will be seen an expression of opinion from our agricultural reporter as to the suitability of the Johnstone River country for the growth of coffee. Some time ago we recorded the success attained in this industry by Mr. Costello, of the Millicent Plantation, at Mackay. In one respect, at least, that success continues to be marked —namely, in the quality of the manufactured article. Travellers on visiting in and about Mackay frequently remark upon the excellence of the coffee procurable there, both at the hotel tables and in private houses, and, upon inquiry, are informed that most of the coffee used is the product of the district, and from Mr. Costello's plantation. So well and favourably known is the article, that it commands a higher figure in the open market than imported coffee, which clearly proves not only that the district is well adapted for its production, but also that Mr. Costello understands its manipulation. It is difficult to induce Queenslanders to experiment with anything new, but coffee is pretty sure, in time, to become one of our staple products. Frost is decidedly injurious to the plant, and drought is also very hard upon it; but in localities where the temperature is moderate when at its lowest, and an average amount of moisture can be relied on to sustain the vigour of the plants at all seasons, there is a very fair assurance of success.—*Queenslander.*

Mr. Morris's Report.—In the recently issued annual report on the public gardens and plantations of Jamaica, Mr. Morris mentions an interesting experiment made upon a plantation of *Cinchona Succirubra* trees. It had been intended to harvest a full crop of bark from these trees, but it was decided instead only to "shave" them, in order to determine which method of collecting the bark would be the most profitable. The total number of trees "shaved" was 2,144, which yielded 5,218 lb. of wet bark, or an average of 2·34 lb. of bark per tree, the average weight of bark brought in each day per man being 50¼ lb. Twelve months subsequently it was found that not a single tree had suffered from the treatment to which the plantation had been subjected; on the contrary, the renewal of the bark had gone on in a most uniform manner, and the trees were then in a condition to yield another crop equal, if not superior, to the previous one. Mr. Morris also reports that the demand for "Jamaica quassia," the wood of *Picræna excelsa*, has greatly increased lately, "owing, it is said, to its utilization as a substitute for hops." The exports of this wood from Jamaica last year amounted to 1,815 tons, of the value of £3,631. Another plant which has also come into prominence as a hop substitute is the Jamaica "bitter bush" (*Eupatorium villosum*), which is common in many waste places in the island. It is said to have an agreeable aroma and contain a bitter principle which has long been recognized by the natives.—*Pharmaceutical Journal.*

Chinese Plant Acclimatisation in the United States. —We take the following from the *Times*, but decline to be responsible for the accuracy of the statements made:—Considerable interest is being taken in America in the acclimatisation of plants, and among them it is proposed to experiment upon the aquatic vegetables of China, which are valuable for food and economic purposes, and are easily cultivated in rice regions and marsh lands generally where water does not freeze or freezes but slightly. The most noteworthy are the Water Caltraps (Trapa bicornuta) (Ling-chiaco), called the Water Chestnut on account of its flavour, a pleasant fruit that requires no cultivation and can bear a very severe climate. The Water Lily (Nelumbium speciosum) appears to be identical with the Egyptian bean of Pythagoras, and is much used for food, being rich in starch, while both root-stock and seeds are alike edible. Its leaves make capital wrapping paper, and its flowers are strikingly gorgeous. The Chiaopai and the Chin-tsai are both varieties of the water Celery, which are planted on Bamboo rafts covered with mud, forming floating gardens similar to those of ancient Mexico or modern Kashgar. A most useful and valuable plant also is the Tieh-shu or Iron tree, which has the curious property of absorbing and assimilating iron, and this is cleverly taken advantage of when it shows signs of decadence, nails being driven into its trunk, and thus giving a new lease of life. (?) The Tiao-lan is another singular plant, which flowers only when taken from the ground and suspended from a ceiling. (?) The Chin-ch'i is the valuable product known as "golden varnish," used to adorn the glossy signboards of Chinese streets, and is furnished by a tree called the Ch'i-shu or Varnish tree, but it possesses an element of danger in a poison which causes acute inflammation of the skin. Even the native dealers in varnish cannot escape, though they suffer less than foreigners, and particularly Americans. The remedy of the country is rather peculiar, being the application of crab's liver and a decoction of Pine shavings.—*Gardeners' Chronicle.*

The Value of Sandy Soil for purposes of cultivation is not generally recognised. There are a few here and there who have had opportunities of observing the results obtained from such soil, and who are favourably impressed as to its value, having had proof of its excellence. Some of the best and most productive fruit-gardens in Queensland at the present time are almost purely free sand. The Botanic Gardens at Rockhampton, and several of the most noted gardens in that locality, are either altogether or largely composed of sand. Two of the most profitable fruit-gardens in the colony at Mackay, one owned by Mr. Barnes and the other by Mr. Armitage, are likewise sand; and, in every instance where intelligence and skill have been brought to bear upon such land, very satisfactory results have been obtained. As may be expected there are well-defined limits as to the capabilities of such soils, more particularly as regards fruit culture. As a rule pine-apples are exceedingly thrifty in sandy soils, especially if allowed sufficient space, and the soil is worked deeply, with an occasional dressing of some good fertiliser. The grape vine is also succeeding far beyond expectations in deep sandy loams, as for instance Mr. Bassett's vineyard, near Roma. The coconut and the date palms are proving thoroughly at home and vigorous under similar circumstances. With the orange and the citrus family generally it is different. As a rule these do not remain in vigour and productiveness long in such soil. There are, however, exceptional cases, which make it extremely difficult to lay down any hard and fast rules with reference to these valuable trees; for notably in many cases orange trees grow and bear well in sandy loams, but only in situations where they can root deeply without coming in contact with injurious or wet subsoils. The mango is very vigorous and productive in sandy soils; not so the jakfruit, nor yet the apple, the pear, or the plum. But sand is found to be eminently adapted for the growth of vegetables. Owners of sandy land in the suburbs of Melbourne can outdo in nearly every particular the attempts made in market gardening on strong black loamy soils. With a constant supply of good manure sand may be made immensely productive, and allowing for the cost of the fertilisers is even then more cheaply and remuneratively worked than stronger soils. Any of our readers who will try experiments with sand lying well for drainage will quickly realise the correctness of the above remarks. The question is sometimes asked: "What benefit can trenching loose sand be?" Experience proves it to be very beneficial, and, as facts are very stubborn things, we like always to give way to them, even when the reason does not appear. —*Queenslander.*

SILKWORM CULTIVATION.

BY U. S. VICE-CONSUL JOHN GRIFFITT, OF SMYRNA.

The efforts that are being made at present in the United States to extend the culture of the silkworm leads me to make this report, trusting it may be useful.

I have been engaged for many years in raising silkworms, my object being the study of their diseases, and, after years of experiments, have succeeded in obtaining healthy grain, the basis of success in silk culture.

I was induced to make these trials in the hope of alleviating the losses that the peasants in Turkey have suffered for the last twenty-five years, and have endeavoured to interest the governors of this Vilayet in my work, in order that I might obtain the moral support of the government, but thus far without success.

The lost suffered by Turkey since 1857, when the silkworm disease first spread so violently, is incalculable. I remember the time when the wife of every gardener in the vicinity of Smyrna obtained from her crop of cocoons a sufficient return to enable her to pay for the clothing of her family for the entire year. This fatal disease swept away our beautiful indigenous races, and this branch of industry was almost abandoned. Many mulberry trees were uprooted, those that were retained being kept by the gardeners solely for the use of their branches.

There were at that time three large silk reeling factories, worked by steam, where hundreds of women were employed. Work had to be abandoned for want of cocoons. The Japanese race was introduced later on, with but partial success. There is a very great difference between the indigenous and the Japanese races; it requires at least double the number of the latter to give the same weight in cocoons; that is to say, if it requires 250 fresh cocoons of the indigenous race to weight a pound, it requires 500 of the Japanese, and the quality of the silk is much inferior.

I obtained some years ago a quantity of indigenous grain of a very fine race, but very much diseased. I raised the worms from the moment they were hatched in seperate cells, in order that the diseased ones might not infect the healthy (all the worms of a diseased moth are not diseased), and from the few healthy ones I obtained my present race, which I have since then continued to improve, and I now find it in every way superior to all other races I have raised, not only as to the vigor of the worm, but also as to the weight of the cocoon and the quality and quantity of the silk it yields. From one ounce of 30 grammes I obtain invariably from 150 to 155 pounds of fresh cocoons, 12 pounds of which, just taken from the brushes, yield over one pound of silk of the best and finest quality. Another great advantage of my race is that it has not more than 4 to 6 per cent of double cocoons, while other races have from 15 to 30 per cent.

In my experiments in raising grain, I find that double cocoons should never be used for reproduction. On the contrary, they should be carefully avoided, as the worms obtained from grain the moths of which issued form double cocoons the next season.

All the grain I raise is manufactured on the system of the distinguished Pasteur, to whom sericulture owes everything in the regeneration of the silkworm. Each moth is placed on a small cloth to lay its eggs, and when finished the size of about a silver dollar I place my grain in thin layers in a room heated with an earthenware stove and gradually bring the temperature to 70° Fahrenheit, taking care to keep a vase of water constantly on the stove. The grain begins to hatch in six or seven days, and continues to do so for four or five days. I throw away the last day's issue, as the worms are not numerous, and weak, although not sickly. Each day's issue is kept apart; to the first day's issue I give two feeds of leaf, cut up very thin with a clean knife, and I give an extra feed to each day's after-issue. The first day's issue I place on the lowest frame of the stand, those of the second day on the one above, and so on. The object of this is to enable the worms of the last day's issue to reach the others in their first molt, as the higher the worms are placed on the stand the greater is the heat, and this, joined to the extra meals, enables them to make their first molt with those hatched earlier, thus forming a regularity in the education. In the second, third, and fourth ages I feed my worms four times a day, at 5 and 10 a.m., and at 3 and 8 p.m. The feeds are given with great regularity. In the last age they are fed constantly from 5 a.m. to 11 p.m., and when I raise worms in my large nursery I employ extra hands to continue feeding them during the whole night, not in large quantities, but never allowing them to remain without food. It is indispensably requisite that the worms should not be crowded, especially in their first ages. I give to the worms of one ounce of grain, in their first age a space of 2½ square yards; in their second age, 5 square yards; in their third, 10 square yards; in their fourth age, 25 square yards; and in their fifth and last age there should not be more than 500 or 600 worms per square yard. The leaves of the wild mulberry are preferable for the first three ages, and the leaves of the grafted mulberry should be given for the fourth and fifth ages. The leaves should be gathered after the dew has evaporated, and if wet by rain they should be dried before they are given to the worms. The leaf is cut up to the end of the third age; after that the leaves are given entire to the worms.

I clean my frames twice during the second, third, and fourth ages. Once immediately after their first meal, after their molt, and again the day before they began to molt. This is done by placing sheets of thick paper, pierced with holes sufficiently large to allow the worms to pass through. These pierced sheets of paper are placed on the worms, leaves are placed on them, and in a few moments the entire batch will crawl upon the leaf. The papers with the worms on are then raised and placed upon a clean frame; if a few should remain in the litter I put them apart from the others. The litter should be raised very carefully; no dust from it should be raised very carefully; no dust from it should be allowed to spread in the room.

The last age of the worm is certainly its most critical one, and requires the greatest care. At this period the worm eats twice as much as during its first foor ages, and the litter remaining on the frames, together with the dejections of the worms render the air impure and unhealthy. Consequently the frames should be cleaned frequently, and there should be a constant renewal of fresh air. Diluted chloride of lime should be kept in each corner of the room during the entire period of the fourth and fifth ages.

Five days after the worms have formed their cocoons they should be taken off the brushes with great care, for if any diseased worms remain on the brushes in a state of putrefaction the good cocoons would be soiled and consequently depreciated in value. All imperfect cocoons should be separated and exposed to the sun for some days to destroy the chrysalis; the good ones steamed. The steaming process for destroying chrysalides is far preferable to any other; the silk is not injured thereby, as it is apt to be by baking or exposure to the sun. I steam them for twenty minutes, the water constantly boiling, and this I find sufficient to destroy the chrysalis; I then place on the frames in thin layers to dry, and after this is effected the cocoons should be reeled off as soon as possible.

By raising the worms of healthy grain, such as I have above described, and by following the foregoing directions, it is impossible not to succeed in obtaining a good crop of cocoons. Years' experience has proved to me that, ignorant as some of the educators have been to whom I have given grain, they have invariably obtained a remunerative crop of cocoons, and even sometimes quite as good as my own.—*Mercury.*

OIL OF STAR ANISE.—The *Moniteur de la Pharmacie* states that one of the principal articles of commerce in the district of Hanoi is oil of star anise, which is manufactured on the frontier of Lang-Son. The industry is carried on by Chinese, who extract the oil by submitting the seeds to uninterrupted boiling during thirty-six hours.—*Pharmaceutical Journal.*

THE RUSSIANS AND THEIR TEA SUPPLY.—The following is a St. Petersburg dispatch to the London *Times*:—"The tea plant has lately been introduced near Soukgoum Kaleh, on the Black Sea, and the Russians are confident, it seems, that they will soon be able to do without either Chinese or Indian teas. They are naturally irritated at the thought that after all their efforts at direct importation by the vessels of the Volunteer Fleet, London can still supply Russia with tea more quickly and cheaply than can the Russian merchants, though next-door neighbours to the Flowery Land."

THE CHEMISTRY AND BOTANY OF THE STRYCHNOS NUX-VOMICA INDIGENOUS TO CEYLON.

BY WYNDHAM R. DUNSTAN,

Assistant Lecturer in Chemistry and Physics to the Pharmaceutical Society and Demonstrator of Practical Chemistry in the School of Pharmacy;

AND F. W. SHORT,

Assistant Demonstrator of Practical Chemistry in the School of Pharmacy.

In a previous paper (*Pharm. Journ.*, [3], xiii., 1053) we have described the results of a chemical and botanical examination of the seeds of *Strychnos Nux-vomica* which come into England under the names of "Bombay," "Cochin," and "Madras." The results of this investigation indicated that the "Bombay" seeds, which were at once the largest (*S*=20—22 mm.) and finest in appearance, contain the greatest quantity of alkaloid. In one case, a specimen of the "Bombay" seeds yielded the highest amount (3·9 per cent) of total alkaloid that had yet been recorded as occurring in the seeds of *Strychnos Nux-vomica*. The "Cochin" seeds were next in order of size (*S*=19—28 mm.), and were also found to occupy a corresponding position in reference to alkaloidal content. Lastly, the "Madras" seeds were the smallest in size (*S*=12—21 mm.), as well as in alkaloidal content. In addition to the size it was noticed that the exterior of the seeds containing the most alkaloid had a very silky texture, due to the presence of hairs adpressed to the surface of the seed; this was particularly the case with the "Bombay" seeds, and on the other hand the silky texture was quite absent from the seeds containing the smallest amount of alkaloid, namely, "Madras." Acuteness of edge also appeared in certain cases to be associated with a large alkaloidal content.

This co-existence of certain well-defined botanical characters in the seeds with the presence of a large quantity of alkaloid was observerd alike in two entirely distinct sets of specimens, the one collected in the year 1877, the other in the year 1883.

This being the case we commenced a botanical examination of such dried specimens of the plant as were available in this country, with the object of ascertaining whether these differences in botanical characters, corresponding to a variation in alkaloidal content, were due merely to a more or less advanced stage of development of the seeds, or whether the differences arose from the seeds originating from more than one species of the plant. This endeavour proved to be futile, for the reason stated in the paper referred to, the absence in this country of authentic specimens of the entire plant, including the fruit and seeds.

Soon after the publication of our results, Dr. W. C. Ondaatje, F. L. S., of Galle, Ceylon, well known as an ardent botanical worker, most kindly offered to collect specimens of the plant which is indigenous to Ceylon, to carefully select fruit and assort the seeds for a chemical analysis. We at once availed ourselves of this very generous offer, and the present paper is the outcome of a chemical and botanical investigation of the specimens forwarded to us with descriptive notes and drawings by Dr. Ondaatje.

The Plant.—The *Strychnos Nux-vomica* grows in the hotter parts of the island of Ceylon, and coincides in general features with the description of the tree from other localities, which is given by Roxburgh and others. The appearance of a branch of the tree with leaves and fruit is seen from the wood-cuts, which are taken from a drawing,* by Dr. Ondaatje, of a tree growing in the Hambantota district, south of Ceylon, an arid and barren country, only important on account of the natural salt formations which occur there and yield a large revenue.

The Leaves.—These are ovate, acuminate, and trinerved. The largest leaves from the tree sketched measured 86·8 mm. in length, from stalk to apex, and 46·5 mm. in breadth; the smallest leaves measured 25 mm. in length and 11·4 mm. in breadth. The leaves, however, appear to vary much in size, although the drawing and above measurements represent typical specimens. Larger leaves from other trees were found to measure from 98·8 mm. to 118 mm. in length, and from 57·5 mm. to 75 mm. in breadth.

The Fruit.—The fruit, the appearance of which is well represented in the drawing, contains the seeds imbedded in a white gelatinous pulp. It varies in size, the same tree often exhibiting both large and small fruits on the same branch. The unripe fruit is green and hard; the ripe fruit has a deep orange colour, and the pericarp cracks when pressed. The largest fruits are about the size of a small orange, and the biggest one examined had a diameter of 56·5 mm. The following are the diametrical measurements of typical fruits and the numbers under which they are subsequently designated:—

No. 1 (fig 1)	...	52 millimetres.	
No. 2	... ...	35 „	(usual size).
No. 3 (fig 3)	...	29·5 „	
No. 4	... ...	25 „	

The larger fruits weighed, when freshly gathered, from 78 to 142 grams, and the smaller fruits from 4 to 12 grams. Within the fruit is a pulp in which the seeds are vertically arranged. This pulp has a very bitter taste, and when fresh is white, but on drying becomes dark brown; the fresh pulp when immersed in alcohol yields an indigo-blue solution.

The quantity of pulp contained in the typical fruits was as follows:—

No. 1 fruit.	Average	amount	of	pulp,	40	grams.	
No. 2 „	„	„	„	„	33	„	
No. 3 „	„	„	„	„	10·5	„	
No. 4 „	„	„	„	„	2	„	

It is stated by the highest authorities that the pulp has no toxic action, and in fact constitutes the food of many birds. Thus Roxburgh,* "the pulp of the fruit seems perfectly innocent, as it is eat greedily by many sorts of birds." Beddome† says the fruit is quite harmless, and the favourite food of many birds. Again, Drury,‡ "the pulp of the fruit is harmless. Birds eat it greedily." According to Cleghorn,§ the pulp is eaten by the hornbill (*Buceros malabaricus*). Bentley¶ quotes Roxburgh to the effect that the pulp is harmless. Flückiger and Hanbury§ rendered these statements unintelligible by showing that both the fresh and inspissated pulp contained strychnine. In view of these conflicting statements we considered it desirable to ascertain exactly the physiological action of pulp. The following physiological experiments were made by Dr. Ondaatje at the Hambanlota Hospital, Ceylon.

Experiment I.—The pulp of a large fruit mixed with about half an ounce of water was given to a large cat. In five minutes tetanic convulsions set in, the body was flaccid, the extremities flexed and rigid. The animal passed an involuntary motion after the first attack, and after successive attacks died within ten minutes of the administration of the pulp. A *post-mortem* examination was made shortly after death. The lungs were congested, the left ventricle of the heart contained fluid blood, but the right ventricle contained clots; the liver was rather congested, the stomach distended with gas, the intestines corrugated. The tongue protruded from between the firmly clenched jaws.

Experiment II.—5·6 grams of the fresh pulp mixed with half an ounce of water was given to a dog about two months old. After eight minutes the posterior extremities became stiff; tetanic convulsions supervened. The dog then fell on the ground, the extremities became extended and stiff, and the body ceased to move. The jaws opened and closed as if the animal were gasping for air, trembling of the whole body occurred, an involuntary motion was passed and the animal died—eighteen minutes after the administration of the pulp. A *post-mortem* examination showed that the right and left ventricles of the heart contained coagulated blood, and that the lungs and liver were congested.

In both these cases the toxic action of the pulp was proved, the animals exhibiting the usual symptoms of poisoning by strychnine. As, however, the pulp was stated to have no poisonous action upon birds, further experiments were made

¶ 'Manual of Botany.'

Experiment III.—Some fresh pulp mixed with a little water was given to a pigeon without any result.

Experiment IV.—The pulp given to a pigeon, as in Experiment III., without any effect.

Experiment V.—0·3 gram of the inspissated pulp was administered to a frog and produced no effect. As the quantity of alkaloid contained in the amount of inspissated pulp administered to the was frog was extremely small, and considering the fact that in the first pulp which was administered to pigeons there would be still less, owing to the large quantity of water present, we requested Dr. Ondaatje to repeat the two last experiments, using larger and weighed quantities of the pulp.

Experiment VI.—2·6 grams of the inspissated pulp dissolved in water was given to a frog and no effect followed, but on administering twenty grains more convulsions speedily came on, commencing at the lower extremities, and death resulted in forty minutes.

Experiment VII.—2·0 grams of the inspissated pulp mixed with water was given to a pigeon. Almost immediately after violent tetanic convulsions set in and the bird died in twelve minutes.

These experiments conclusively demonstrate the poisonous nature of the pulp, and show that its action is mainly, if not entirely, due to the strychnine which it contains. Birds can no doubt consume a certain quantity of the fresh pulp with no fatal effects, for the proportion of strychnine present in the semi-liquid mass is not large, as subsequent analysis shows. Obviously, if eaten to more than this extent, fatal results will ensue.

The conclusions from these physiological experiments were strictly confirmed by a chemical examination of the pulp. For this purpose the inspissated pulp was used, which was prepared in the following way:—The gelatinous pulp was squeezed from the seeds into a wooden bucket, when dirt and other foreign matter was removed, after which the semi-liquid pulp was dried in the sun for one month. The partially hardened mass was then flattened out on a plate and again dried in the sun for one month. A dark-brown firm cake of pulp was then obtained, having a slightly aromatic odour. This was submitted to chemical analysis. We have already (*Pharm. Journ.*, [3], xiv., 1025) described a new glucoside called loganin, which was obtained from this pulp.* In order to estimate the alkaloidal constituents the pulp was dried at 100° C., when it lost 22 per cent of water. The dried pulp was finely powdered and exhausted in an extraction apparatus with boiling chloroform containing 25 per cent by volume of absolute alcohol. The loganin which crystallized as the percolate cooled was filtered off and the total alkaloid was estimated in the liquid by a process which has been described in a previous paper (*Pharm. Journ.*, [3], xiii., 1053). The liquid was well agitated with two successive portions of dilute sulphuric acid, and the alkaloid extracted from the aqueous liquid by chloroform after excess of ammonia had been added. Any loganin which was not removed by crystallization remained in the ammoniacal liquid. The amount of residue obtained corresponded to 2·4 per cent of total alkaloid in the dried pulp. This residue of total alkaloid was now qualitatively tested and found to contain both strychnine and brucine, which were separated by the process that we have described in a former paper *Pharm. Journ.*, [3], xiv., 290), which is based upon the difference in the solubility of strychnine and brucine ferrocyanides. About 0·2 gram of the total alkaloid was dissolved in about 10 c.c. of a five per cent (by volume) solution of sulphuric acid, the liquid was diluted to about 175 c.c. with water, and then made up to the volume of 200 c.c. with a five per cent solution of potassium ferrocyanide. After constant stirring and agitation during four hours the precipitate was filtered off and washed with dilute sulphuric acid (0·23 per cent) until the washings were free from bitterness. The moist precipitate was then decomposed by the addition of ammonia hydrate, and the strychnine extracted from the liquid by successive portions of chloroform. The following table exhibits the results of the chemical examination of the pulp.

Chemical Analysis of the Inspissated Pulp of the Fruit of Strychnos Nux-vomica.

100 parts contain:—

Water	22·0 parts
Strychnine...	1·4 „
Brucine...	1·0 „
Loganin...	5·0 (nearly)
Ash	5·0 „
(K_2CO_3, Na_2CO_3, $CaCO_3$, Li_2CO_3, etc.)	
Fixed Oil, Mucilage, Gum, etc.	65·6 „

It will be observed that the proportion of strychnine to brucine in the pulp is much higher than in the seeds, the strychnine constituting more than one-half of the total alkaloid.

The Seeds.—The largest fruit examined contained fourteen seeds, of which seven were abortive. Another large fruit contained ten seeds, of which one was abortive. The number of seeds was counted in a great many specimens of fruit.

Five hundred and ninety-three fruits were gathered and examined. There were of—

No. 1, 108 which contained 434 normal seeds and 52 abortive seeds.

No. 2, 245 which contained 468 normal seeds and 52 abortive seeds.

No. 3, 165 which contained 190 normal seeds and 7 abortive seeds.

No. 4, 75 which contained 77 normal seeds and 21 abortive seeds.

The number of seeds found in the typical fruits was as follows:—

No. 1 contained from 2 to 9 seeds, usual number 4.

No. 2 generally contained 2 seeds, sometimes 3 and 4, with abortive ones.

No. 3 generally contained 1 large seed, rarely 2.

No. 4 generally contained 1 large and 1 small seed. When 2 seeds occur both are generally abortive, or sometimes the smaller seeds alone is normal. The large and small seeds occur in the same fruit. Thus, a specimen of—

No. 1 contained 3 large seeds, 1 small seed, with 4 abortive seeds.

No. 2 contained 2 large and 2 small seeds, none abortive.

No. 3 contained 2 large and 2 small seeds, none abortive.

No. 4 contained 1 large and 1 small seed, none abortive.

The seeds had a silky exterior and were found to be coated with fine hairs. These hairs, which consist of elongated cells of the testa, exhibit an extremely interesting structure when examined microscopically. Their structure has often been described, but we are not aware that they have ever been sketched. The woodcut is from a drawing by Dr. Ondaatje. The large seeds weighed from 2 to 2·5 grams, the smaller seeds from 1 to 1·5 grams. The diameter of the seeds ranged from 13·5 to 22 mm., the circumference from 44 to 66 mm., the thickness from 3 to 5 mm. The edges were usually rounded (*Cf.* and appended table). A chemical analysis of the seeds was now made. They were dried at 100° C., powdered, and the total alkaloid estimated by the process which we have previously described. In the first place average specimens of the seeds contained in the typical fruits were analysed (see appended table.)

In considering the results obtained, several factors have to be taken into account. It has already been seen that the biggest fruits do not contain the largest seeds; thus the average seeds of both No. 1 and 2 fruits are about the same size, but the number of seeds contained in these two fruits is not the same. No. 1 fruit commonly contains four seeds, but No. 2 fruit usually contains only two seeds. It will be seen from the analyses that other things being equal the fewer the number of seeds in the fruit the more alkaloid the seeds contain. Thus the average seed from No. 1 and 2 fruits is about the same size, but No. 2 fruit only contains half as many seeds, and it is found that the seeds of the latter fruit contain more alkaloid than those of the former. Fruit No. 3 contains seeds, an average specimen of which is slightly smaller than the seeds from fruit No. 2; but the former fruit usually contains only half as many seeds as the latter, in fact, commonly only one seed is present. It is seen that the seeds from fruit No. 3 contain more alkaloid than the seeds from fruit No. 2. Finally, the average seed from fruit No. 4 is decidedly smaller than the seeds from any of the pre-

* A specimen of loganin is now in the Museum of the Pharmaceutical Society.

ceding fruits, but as this fruit usually contains but one seed, this compensates to a certain extent for deficiency in size, and it is noticed that these seeds contain rather more alkaloid than the seeds from fruit No. 1, although this fruit yielded seeds which were larger. The proportion of strychnine is fairly constant, being a little more than one-third of the total alkaloid.

We now made further analyses to elucidate the important question alluded to in the early portion of this paper, namely, whether increase in the size of the seed corresponded with an increase in alkaloidal content. For this purpose the largest seeds were selected from fruit No. 1 and also the smallest seeds from the same fruit; these two sets of seeds were then separately analysed, with the results recorded in an appended table. These results conclusively show that the largest seeds contain the greatest amount of total alkaloid, although the increase in alkaloid in the present instance has been in brucine, the quantity of strychnine in both seeds being the same. This latter point deserves fuller investigation in other specimens.

General Bearing of the Investigation.—The principal experimental results of this inquiry are summarized in the appended tables. Apart from minor points that have been elucidated, the following important conclusions have been arrived at:—

The poisonous nature of the pulp of the fruit of *Strychnos Nux-vomica* has been conclusively demonstrated by physiological experiment. The chemical examination of the pulp has shown that it contains, besides the alkaloids strychnine and brucine, a new glucoside which we have called loganin.

The glucoside loganin has been shown to exist in small quantity in the seeds.

The alkaloidal content of the seeds of *Strychnos Nux-vomica* is directly as their size and inversely as their number in the fruit.

The seeds obtained from the *Strychnos Nux-vomica* indigenous to Ceylon are especially noteworthy for their extremely high alkaloidal content. Every specimen examined has contained much more alkaloid than we have previously shown to exist in the richest specimen of nux-vomica seed that enters the English market—"Bombay" (3·90 per cent). One specimen of the seed (from No. 3 fruit) yielded a very much larger quantity of alkaloid than has ever been supposed to exist in the seeds of this plant (5·34 per cent). This is a matter of great importance from a commercial standpoint, for the plant is very abundant in Ceylon, and at present none of the seeds are exported from the island.

This communication bears witness to our great indebtedness to Dr. Ondaatje; but for his notes, drawings, specimens and his unwearied interest in the work, the results described in this paper could never have been reached. Dr. Ondaatje's drawings are of the greatest value not only on account of their high artistic merit, but also for the great accuracy with which the botanical characters are depicted. The illustrations to this paper are probably the most faithful reproductions of the nux-vomica plant that have yet appeared.

—*Pharmaceutical Journal.*

THE FRUIT TRADE IN NEW ORLEANS AND HONDURAS.—An American paper says that eight years ago a steamer was rarely seen in a port of Spanish Honduras, and all the trading was carried on in schooners. Now there are six steamers plying regularly between New Orleans alone and the Honduras ports, all engaged in the fruit trade, and there is not a day but a steamer is seen landing at short intervals along the coast and at the Bay Islands, taking on the cargoes of Bananas, Coconuts, Pine Apples, Limes, Lemons, and Oranges. A steamer will bring to New Orleans 15,000 to 20,000 bunches of Bananas, and an equal number of Coconuts. The effect of this trade has been to stimulate the cultivation of fruit in that lazy country and increase the price. Coconuts now bring 20 to 30 dollars (about £4 to £6) per thousand on the coast, and at these prices the cultivation is very profitable. Land is cheap; it may be had for nothing in some places, and for a trifle in the best regions. It requires seven years for a Coconut tree to bear, but from that time on it yields a never-failing crop of 120 to 150 nuts a year. The Banana bears a crop of bunches nine months from the time the sprout is planted, and as the soil is very rich the yield is large—larger than that of any other article of food grown in the same area.—*Journal of Horticulture.*

A FEW WORDS ABOUT TEA IN THE UNITED STATES.

BY IGNORAMUS.

Perhaps the question of tea culture may be considered exhausted in our region (near Summerville, S. C.), when we see the failure of the government tea farm, which, for awhile, promised such favorable results. Any one now visiting the neglected grounds would sigh over the miserable condition of the plants, hundreds dead and as many more leafless and dying. The farm is deserted, as I believe the government refuses further aid to the scheme.

Let me now mention a few facts with regard to tea culture, which cannot be gainsaid.

Six years ago we obtained from the Agricultural Department, at Washington, some small, delicate tea plants, which were carefully planted in the poor, sandy soil of our Pine-land garden. For awhile we were rather hopeless as to their surviving, many of them looked yellow-leaved and sickly; but gradually they assimilated themselves to the uncongenial soil, and put out both buds and flowers. Now, after five years of growth, we have strong, dark, shining-leaved bushes, perfectly healthy, having withstood untouched the terrible killing frosts of the past winter, which have ruined our orange trees and oleanders, and even affected our roses.

We believe the secret of the culture of the tea plant is, that where it is planted, there it must remain, undisturbed. We never dig around our bushes, the soil being so light and sandy, generally removing the weeds by hand, or with a very light hoe.

A neighbour who had his tea plants long before we got ours, has handsome, spreading bushes growing in the same sandy land as ours; some seeds from his plants have by accident fallen among the debris along the high road, and have grown into nice plants, which can now be seen there, showing how perfectly easy is their culture. If the above account proves interesting, I shall have great pleasure in giving further information as to tea raised from seed saved from our own bushes.

[There have been singular mistakes made from the first in regard to tea culture in the South. Some twenty-five years ago the government thought it would like to know whether the Chinese tea would grow in the South, and they sent an agent to China to get seeds. At that very time, hundreds of tea trees were growing in the South, producing seeds, and nurserymen were raising plants for their trade both from these seeds and from cuttings. Any nurseryman could have told the government that the tea plant would grow very well in the South, and on a year's notice could have furnished, under contract, as many plants as desired for distribution. But the seed came, plants raised, and distributed everywhere, and that was about the last of it.

During the last few years the government again tried its hand. Again it did not appeal to nurserymen or tree growers of experience, and again we have the result in the announcement that it "can't be done."

Now, this is all nonsense. The tea plant has been grown successfully, and is still growing successfully in many parts of the South. Tea has been made from the leaves as good and as cheap as the Chinese ever made. Let the government give but a bounty—protection, if you like to call it—for a few years for private enterprise, and we will guarantee the success of the Chinese tea plant as a tea product in America. We do not need hundreds of acres for experiments. Give premiums for an acre, or half an acre, and for teas of various qualities from the leaves, and give guarantees that these premiums shall continue from year to year, till experience is improved on, and there will be no more reason found against the permanent success of the enterprise, than there was against beet root sugar culture in France. That would never have been a success but for the protection Napoleon gave it. —ED. G. M.]—*Gardeners' Monthly.*

FORESTRY EXHIBITION AT EDINBURGH.

(*Continued from page 359.*)

JAPAN.—Owing to the varied character of its climate Japan possesses a singularly rich flora, as will readily be seen in the numerous and somewhat interesting nature its exhibits. In the north flourish vast forests of Oak a Pine; in the south the Cycas, Tree Ferns, the Banana, the Bamboo, Bignonia, and Myrtle, delight the eye with their grace of form and wealth of colour. The landscapes are also richly diversified by clusters of Hydrangeas, Camellias, and Azaleas, which here attain a luxuriance and beauty almost unknown in Europe. Amongst the trees which clothe the mountains are the Chestnut, Maple, Beech, Elm, Lime, Elder, and Cypress. Japan also possesses amongst its varied collection of ornamental Conifers several of great value as timber trees, and which have been critically studied and figured in recent volumes of the *Gardeners' Chronicle*. Amongst these may be specially noted Retinospora obtusa, a splendid slab of which is exhibited, which clearly shows the great size this tree attains in its native country, the wood of which might, at a casual glance, be readily mistaken for that of the Californian Redwood, than which, however, it is of superior quality, being extensively used in ship building, for the erection of houses, and for turnery. Other varieties of the same wood are also shown, but these seem of inferior quality and destitute of the rich colour so characteristic of the normal form.

The Japan Cedar (Cryptomeria japonica)—a tree much prized in this country for its ornamental appearance and general suitability for our climate—must, from the sections of wood here shown, attain a goodly size in its native country. This tree attains to a height of 130 feet and is much used in Japan for bordering the high road. Various slabs of the more ornmental timbers are also on view, such as the Bird Cherry, Maple, Juniper, Yew, and Camphor-wood, the latter remarkable not only for its fragrant perfume but for its beautiful graining as well. Of what we have styled ornamental woods there is exhibited an exceedingly neat trophy, showing in combination nearly 100 specimens of such as are valuable either for quality, beauty of graining, or colour. Amongst the various forms of Oak found in Japan, several of which are evergreen, none are of any particular value as regards quality of timber, though for ordinary purposes they are much in request. From the bark of one species of Oak cork is obtained, while others are valuable for their edible fruit or for the dyes obtained. The Camphor tree (Laurus camphor), found in most of the forests, occasionally attains to huge dimensions. One, visited by Kaempfer, in the island of Kiusiu, is supposed to be upwards of 1,000 years old. The Lacquer or Varnish tree (Rhus verniflua) furnishes the gum with which the Japanese heighten the brilliancy of their *papier mâché* articles. The Wax tree (Rhus succedanea) yields seeds from which wax for candles is obtained by compression. It thrives best on barren and stony ground, ripens in its eighteenth year, and afterwards declines.

Another valuable tree is the paper Mulberry (Broussonetia papyrifera), whose bark supplies the paper of which the Japanese make such extensive use. Several specimens of clothing made from one of the climbing plants are also exhibited, as well as Willow basket-work, woods for engraving purposes, and a miscellaneous collection of useful articles ingeniously made by the natives from Bamboo splints. An interesting collection of butterflies, dragon-flies and beetles is to be seen, as also specimens of the ordinary silkworm, the culture and rearing of which is an extensive Japanese industry. Specimens of silk procured from the different varieties of the worm—some of which are fed on the Mulberry leaves, and others on those of the Oak—are also exhibited. To those interested in the manufacture of charcoal an examination of the models of kilns will be highly instructive. One of these is made of stone, in which Oak and the better classes of wood are carbonised, and the other, which nearly approaches our own method of kiln-burning, is used chiefly for the rougher woods. The former method, from the quantity of charcoal produced—300 lb. from about 1,000 lb. of wood—is well worthy of imitation by those who have the supplying of this commodity for estate purposes. An interesting collection of about 100 dried specimens of the leaves of different varieties of Maples is conspicuously arranged in frames made of different woods, and give to the observer a fair idea of the numbers of this interesting family now under cultivation in Japan.

A tree-transplanting machine of good design, various wood-working tools, wooden water-pipes ingeniously constructed, and a timber-pond, are all exhibits of a practical nature. These ponds exist in large numbers in Japan, and are in construction somewhat similar to those used on th

Continent. In our own country the art of preserving timber by subjecting the logs to the influence of salt water has long been known, and is, in many sea-side districts, extensively practised even at the present time. There are likewise exhibited models of rustic arbours and fences, a collection of cones and seeds, specimens of dwarfing and grafting, in which the Japanese are very accomplished, and many other objects of interest which space will not allow our dwelling on at present.—*Gardeners' Chronicle.*

ECONOMIC PLANTS IN QUEENSLAND: BRISBANE BOTANIC GARDENS.

The annual report of Mr. Pink, the Head Gardener of the Brisbane Botanical Gardens, which has recently been published, contains many items of much interest. Ever since the formation of the colony, these gardens have played an important part in the fostering of agricultural and horticultural pursuits. The amount and variety of the plants which have been thence distributed to all parts of the colony we are not in a position to state; that they have been most extensive in quality and valuable in their effects on our budding industry, is patent to all. We notice that during last year between 4,000 and 5,000 economic plants have been distributed, including *Coffea Arabica*, *Coffea Liberica*, *Thea bohea*, *Thea Assamica*, *Theobroma cacao*, cinchona in several varieties, vanilla, *Aleurites vernicia*, &c. Some 7,000 plants of various kinds, such as trees, shrubs, and border plants, have also been supplied for public institutions, such as Government offices, Queen's parks and reserves, public recreation grounds, municipal corporations, hospital grounds, State school grounds, and the like. We also note that the distribution of ornamental pot plants have been almost entirely discontinued except under special circumstances, as such plants can now be obtained at trifling cost from any nurseryman. It is in its vocation of distributing the various economic plants, that these gardens have conferred the greatest benefit on the colony; and in that light we look on the facts connected with these as of far more public importance than on the work done in spreading merely ornamental trees and shrubs. Mr. Pink gives us some very interesting facts in reference to some of these matters which we lay before our readers, without any apology, as being of almost universal interest.

Speaking of the distribution of economic plants, Mr. Pink says:—"The distribution of economic plants has been continued on a large scale, the demand for all kinds having been unprecedented, especially for coffee. Economics being made a speciality, no application for such plants is ever refused, so far as they can be supplied; and a stock of coffee, tea, cocoa (*Theobroma cacao*), cinchona, vanilla, &c., is always kept on hand ready for packing at a moment's notice. A number of named grafted mangoes obtained from India have been distributed amongst the most likely growers in the North. Plants of the Brazilian nut (*Bartholletiæ excelsa*) have been introduced, I believe for the first time, but the demand for them was so great that not a tithe of the applicants could be supplied. It is my intention to apply for a further supply to the Royal Botanic Gardens of Kew, to the authorities of which institution this colony is greatly indebted for their prompt and liberal response to all my applications for economic plants, many of which it would be impossible to obtain from any other source." Of the coffee in the Gardens he says:—"The coffee plants in the Gardens here have again borne an excellent crop; the present crop being estimated by several Ceylon and Fijian planters who have visited the Gardens at the rate of 10 cwt. per acre. Coffee is being planted largely in several districts, notably about Cairns and on the Blackall Range. The latter district I intend visiting shortly to collect ferns for foreign and intercolonial exchanges I then hope to visit the coffee plantations there, to induce the growers to plant cinchona, for which I think the district should prove most suitable." This brings us naturally to the cinchona experiments, and on this head we learn that cinchona still promises well. The plants put out three years ago in the economic beds are thriving admirably. One plant of *Cinchona officinalis* is showing flower freely; therefore we may hope for acclimatized seed. The position of the cinchona planted in the Gardens being rather low, and being anxious to watch its development in a higher locality and under different conditions, I was kindly permitted by Mr. A. J. W. Nightingale to plant a plant in his garden on the high ridge of Breakfast Creek. This plant (*Cinchona succirubra*) has made equally good progress and is also showing flower, and these I consider conclusive proofs that cinchona can be grown almost anywhere in the neighbourhood of Brisbane—of course the higher the elevation the better, and further north I have no doubt it would become a great success. Hitherto great difficulty has been experienced in raising cinchona plants from seed. Cinchona seed of several varieties has been imported and distributed throughout the colony, but few have been successful in raising plants in any quantity. In the Gardens here every known method as carried out in Ceylon and South America, was tried for some time without any uniform success; but we have found the following plan successful with all varieties:—A flower-pot or seed-pan is filled with crocks or draining material quite to the rim. On the top is placed dead moss about an inch in thickness—sphagnum moss is best, but any kind will answer. After the moss has been well watered the seed is sown on the surface, sprinkled with water, and the pot or pan placed in a warm position. In about ten or fifteen days the seed commences to grow, and when in rough leaf is pricked out, taking a little moss with each plant. Then they require only ordinary care.

Mr. Pink speaks quite as hopefully of the hop plant of which he says:—"Experiments have also been made with the hop plant (*Humulus lupulus*), with results far exceeding my expectations. In the first season the produce has been equal to 10 cwt. per acre. This is an extraordinary production; in England 4 cwt. per acre the first year being considered extremely good, and this confirms my opinion that the hop might be cultivated in this colony with every success, especially where irrigation can be resorted to."

All these crops must be looked on, as yet, as largely experimental. But the resources of the Botanic Garden are not confined to economic plants while in this stage. A great deal of most valuable work is being done in the way of distributing new and valuable varieties of sugar cane, as many of our readers know. On this subject we learn that over 100 tons were distributed last season. The past season having been very dry, the cane has not made its usual growth, but judging by comparison, it has done exceedingly well. A large collection of about forty varieties has been received from Mauritius. There being no ground unoccupied at the nursery, the cane has been planted in the Botanic Gardens until ground can be spared at the nursery. Although all the varieties received from Mauritius are under distinct names, it is quite possible some of them may prove to be identical with kinds already cultivated here under other names.

Nor are economic and valuable timbers neglected. It appears that at the Oxley Reserve, which, by the way is quite occupied, there are now ready for transplanting about 20,000 trees of various kinds, including cedars, olives, silky oak, English oak, English ash, poplars, and Moreton Bay chestnut; also arrowroot-producing plants.

All this is eminently encouraging. While this report gives us some idea of the large and important work discharged by the head gardener, it also indicates how wonderful and varied are the agricultural resources of the colony it is our good fortune to inhabit. Here we see efforts being made, and that too with every prospect of success, to introduce among our articles of staple produce crops so far apart in original *habitat* as hops, coffee, cocoa and cinchona. All of these are amongst the most valuable and remunerative products of the soil, and all of them, Mr. Pink's experiments prove to be adapted to our soil. At least that much can now be said of the coffee, hop and cinchona.

While on this subject we note with much pleasure that a long-felt want is about to be supplied. We are told that "The Colonial Botanist (Mr. F. M. Bailey) has also prepared a catalogue of all the plants growing in the gardens, which is now ready for printing. When published this will be very serviceable to this establishment, especially in facilitating exchanges with other public gardens and correspondents, and I would respectfully beg to recommend that copies should be obtainable at as reasonable a cost as possible, for the convenience and information of the public and strangers visiting the gardens."

In closing this article, we cannot help congratulating ourselves and the colony on the possession of so valuable an institution as are the Brisbane Botanic Gardens. The good effected by it is silent and unobserved. But it is none the less wide-spreading and permanent. Nor can we withhold our need of praise from the head gardener. Mr. Pink is evidently the right man in the right place. We had in Mr. Walter Hill a faithful, indefatigable and highly intelligent public servant. It is very pleasant to know that in his successor we have all these qualities still embodied, together with much of that increased knowledge which every succeeding generation is able to attain. In all matters appertaining to his profession Mr. Pink is abreast of the age, and is certainly the right man in the right place.—*Planter and Farmer.*

THE DEATH OF PLANTS.

Life is one continual series of changes—

"By ceaseless action all that is subsists."

The result of these changes is gain or loss, waste or repair, now one, now the other; or occasionally (and indeed generally) both simultaneously. While a proper balance and equitable adjustment between gain and loss exists, the plant lives and is healthy. Directly the balance is disturbed the plant may live indeed, but it becomes unhealthy; and if the disturbance continue—if waste overtake repair—if nutrition be persistently impaired, still more if it be arrested, the plant inevitably dies. This is that gradual and slow, but sure march of destiny, which comes sooner or later to all living things at their appointed time. That time comes when the tissues are—from that degeneration of their substance which may be a morbid process resulting from injury, or which may be merely the necessary result of the growth and maturation of the plant, or from the failure of supplies—no longer able to carry on their life-work. The period in question varies as to its occurrence. A Wheat plant uses up its life within a few months, an Oak tree within a few centuries, and there is every intermediate period.

But, in addition to changes which are the result of an inevitable march of events, death in plants sometimes comes suddenly from violence, life action is arrested in its full flow and tide, and by much the same essential causes as those which extinguish the life of animals. The death of plants is the death of protoplasm. Prevent the access of oxygen to the living cell, and the movements of the protoplasm will be arrested and ultimately cease altogether. The properties and functions of protoplasm have already been explained. It is their destruction and their cessation which constitute death. But the death of a part is not necessarily the death of the whole, and the individual cells of plants are, as a rule, much more independent one of the other than are the individual cells of an animal. A root, or a leaf, or a mass of roots, and a number of leaves may be injured, or even killed, and the plant will still live on, because there are more left behind uninjured; and these, relatively speaking, do not suffer from the damage done to their fellows. A tree may be stripped of its leaves and may still live, because there are cells which are uninjured, and which will do their parts towards compensating the injury. A felled tree by the roadside will often be seen pushing up new shoots in a manner that would be impossible in the case of an analogous injury done to one of the higher animals. The lower the organism, the less special in its conformation and construction, the more independent are its constituent cells. The higher the organism, and the more specialised its structure, the more dependent one upon another are the structural elements of which it is compounded.

Natural death may be described as an exhaustion of the protoplasm—its water evaporates or is drafted elsewhere; and so with its soluble or liquid contents—the insoluble and the useless remain behind. We see this in the case of the leaves every autumn; their protoplasm dries up, their chlorophyll degenerates and disappears; they are emptied of starch and other matters, which are conveyed to some other part of the tree to be stored up for future use by the new growths in the following season, till at length nothing is left but a framework of dry cellulose, a quantity of mineral or earthy matter, and such material as could not be dissolved or transported. In other organs the continuous maturing process at length results in the blocking up of the cells and tubes by continued deposit in the interior. Osmosis can no longer go on between them, for their altered structure prevents it, and in consequence the protoplasm disappears. Just as in human beings, the minute blood-vessels get "bony," or otherwise deteriorated in structure, so do the cells and fibres of plants become unfit to carry on the processes of life.

For the purposes of the cultivator it is very desirable that he give an eye to the way in which plants die, and to the causes which induce death. The subject may be looked at from various points of view. From the structural point of view death may begin in the cells of the root, in those of the stem, in those of the intermediate "collar," or in those of the leaves, and the appearances presented will be found to differ correspondingly.

From a physiological point of view death may result from starvation or from suffocation; the process in each case may be partial and gradual or immediate and complete. Sudden death, or death by violence, results from the injuries inflicted by too high or too low a temperature, electric shocks, sunstroke, strong corrosives, and the like. These destroy life by disorganising the protoplasm, breaking up the tissues, and arresting the natural movements, and cause death by destroying the machinery or paralysing its action. The gradual effects produced by such injurious agencies as noxious vapours from kilns or factories, or as insects, or parasitic fungi, are the same as those produced by starvation or suffocation. In the neighbourhood of towns it may happen that the relative absence of oxygen, or, what comes to the same thing, the inability to use what there is, may conduce to the death of plants quite as much as the direct injury caused by noxious vapours. A perusal of the foregoing chapters as to the food and growth of plants will suffice to show why plants die; and a consideration of their life-history as here set forth will show how the cause that may kill at one stage of active growth may be all but harmless at another stage of growth.

DEATH BEGINNING AT THE ROOT.—When death begins at the root the supply of water, and of the air and food derived from the soil, is cut off, and the plant ultimately perishes of starvation. Death at the root may result from injury inflicted by small parasitic worms, insects, rats, or other creatures—from unsuitable conditions of soil, too much or too little water, deficient drainage, deficient aëration, or from the presence of really poisonous ingredients. If the cause is widespread, so as to involve a majority or the whole of the roots, the consequences are proportionately serious; if only a few are affected the plant may not be visibly or materially injured. The effects will be first and most especially obvious at the point of injury, and at the growing points where the life-functions happen to be going on most vigorously at the time. Thus, if the young shoots and young leaves are in full activity at the time when root-mischief occurs, they will the soonest show the effect of cutting off supplies—they will wither and droop. If the process is slow and gradual the leaves will become emptied of their contents, their chlorophyll will change colour, the plant will assume a sickly yellow look very characteristic to the practised eye. The older portions of the plant, with their reserve stores of water and food, may not immediately suffer; and it is from them that the materials requisite for any effort at repair and reorganization must, if it be possible, be made. Thus a plant may grow for some time after injury, and then suddenly flag, because its reserve supplies are at length exhausted. It follows from this that death from starvation as a consequence of root-mischief is not generally a sudden, but more often a gradual process, the length of time of course varying according to the nature of the mischief, and specially according to the nature and condition of the plant.

DEATH BEGINNING AT THE LEAF.—This may be appreciated from what has been before said as to the functions of the leaf. The leaf is an organ of nutrition, of respiration, and transpiration; if its functions are sufficiently interfered with, death will result either from inanition or from suffocation, or from both combined. The power of resistance that a leaf has may be inferred from its structure. A thick fleshy leaf, with layer after layer of chlorophyll-containing cells, with relatively few pores and a thick skin, is obviously better able to resist injurious agencies than a thin leaf whose delicate texture speedily withers and falls a prey to adverse circumstances.

The fall of the leaf in the case of deciduous trees has been already alluded to. It is only requisite here to say that, under the circumstances, it is a natural process; and it is one that is provided for from the beginning. From a very early stage in the development of the leaf, a special layer of cells has been gradually forming at the base of the leaf-stalk at right angles to the others, which ultimately cuts off the drying and dead leaf-cells from the living tissues of the bark, much as the "drop scene" of a theatre separates the body of the house from the stage at the close of the performance. The leaf is emptied of its contents, and further supplies from below are eventually stopped off by the intervention of the layer of cells above described. A similar process takes place in the disarticulation of branches and of ripe fruits.

When disease or injury affects the leaves while still growing—as in the case of noxious vapours from chemical works or kilns, or in the case of insect injury—its effects are naturally most obvious and most severe at the growing points—the tips and margins of the leaf; and when the margins become thus arrested in their growth, while the disc remains in full activity, the result is a cup-shaped appearance or a crumpled surface resulting from the dead or dying portions having lost their elasticity and acting as a curb on the still growing portions. Sun-burns, and especially the attacks of insects and parasitic fungi, are not so much confined to the margins, at least when the leaf is not in a growing state; they produce their effects in the shape of circular or irregular spots of brown decayed protoplasm. The effects of frost, and the reason it kills, have been explained elsewhere. Nothing, however, can be advanced in explanation of the reasons why some plants of the same species, like the different varieties of Wheat, are so much more tender than others. Death by the leaf is rarely immediately fatal, because there are many leaves, and they are not often all affected in the same way at the same time; and, moreover, in the case of plants other than "annuals," the fall and death of the leaves does not involve the death of the plant as before explained. Even in the case of annuals, the life, like the nutritive matter, goes out of the leaves only to enter the seed.

Successor thus follows predecessor in one invariable rhythm, and although the limits of the individual existence can be but too readily recognised, the real end of life, so far as the whole race of living creatures—whether plant or animal—is concerned, is as incapable of being appreciated by the physiologist as is its beginning.—From Dr. MASTERS' "Plant Life."—*Gardeners' Chronicle.*

COCONUT CULTIVATION IN CEYLON.

The July number of the *Tropical Agriculturist* opens with a very interesting and highly instructive paper on Coconut Cultivation by a veteran planter. "W. B. L." The paper is perhaps not as full with details, modes of culture, &c., as another paper on the same subject which bears evident traces of the same pen, and written nearly a decade back. To those engaged in coconut cultivation, I would advise the careful perusal of both papers, as likely to afford many useful hints. I cannot more than give a slight sketch of the last essay. The best soil for coconuts is said to be alluvial loams, subject to periodical inundation. The next, brown loams, after which come sandy loams. Solid cabook and stiff clays are to be avoided. The nearer the land approaches the level, the better is it for coconut cultivation. Nurseries must be made eight months before the plants are wanted, with 50 per cent more nuts than the number of plants necessary. Those that do not germinate within 5 months are to be rejected as likely to be laggards all their life. The careful selection of seed-nuts is of the first importance. The trees from which the nuts are taken should be mature, healthy and in heavy bearing. The nuts must be thin-skinned and ripe without being dry. Considering the length of life of a coconut tree, it is really a pity that no attention whatever is paid to the selection of the seed-nuts. Any and every nut one comes across is put in the nursery, or plants are bought from anywhere. The beds, we are told, are to be 4 feet wide, and made by digging the grounds 6 inches deep and placing the nuts with the stalk end upwards. After experience, I have a decided objection to placing the stalk end upward, and for this reason, that there is a depression at the stalk, which is directly over the "eyes" of the nut, or the seat of the germ. At the depression, the husk is not, as elsewhere to a certain extent, impervious to moisture. All the moisture taken in at the depression works its way downwards, and by the action of the sun causes a certain amount of fermentation that destroys the germ. If the nuts are placed sideways, these objections are overcome, and the germ is kept constantly moist by the water within the nut—which is not the case in the other position—and offers greater inducement to speedy and successful growth. It strikes me that the information now given to fill up only the spaces between the nuts with soil does not quite accord with what was written by the same writer a few months back, when theorizing on the depth the seed of the different palms ought to be put in the ground to ensure successful growth. In that communication, which was one of a series of monthly reports of a new products estate, it was said that coconuts must be planted with six inches of soil above it. It happened that I had just about that time formed a coconut nursery in the usual style, that is with the top of the nuts peeping out. I was asked why I did not follow the new plan by one interested in the nursery, and as his wishes seemed to lie in the newly-suggested direction, I took no steps to remove from the nuts all the earth that had been washed over them—for, remember, my nursery was below a slope. What was the result? About 90 per cent of the nuts rotted and refused to grow; so much for theories, and for leaving the well-beaten track of experience to follow the attractive paths of theory.*

To return to the essay. The lining must be in squares 25 ft. each way. The holes must be cut with the first rains in March, and must be 3 ft. cube and be half-filled with the top soil and ashes. If this were always followed, we should certainly have strong, healthy plantations, giving good crops without extraneous aid. Instead, we find the general practice is to cut, or which is thought to amount to the same thing, to give orders to cut holes 18 inches every way, into which the plants are put with no attempt to give them a start by putting a little of the rich surface soil and ashes round the nuts. And this is the universal practice amongst those who should know better. Fencing your clearing to keep out cattle is said to be the next step, and a live fence is recommended of either *erandu* or *kaju*. A paragraph is devoted to the discussion of secondary crops on coconut clearings, and much speculation is indulged in. The writer has no objection to any secondary crop which covers the cost of labour, pays for fertilizers in the place of what it removes, and leaves the owner something besides. I venture to believe he is not singular in this, as this object is the sum total of the aspiration of every reasonable cultivator. The usual secondary crops of the goiya system do not, it is said, meet these conditions, and kurakhan, it is said—on what authority we are not told—consumes a vast quantity of phosphates and nitrates. I quite endorse the writer's suggestion that it would be better to grow chillies in the place of kurakhan, manioc and sweet potatoes; for chillies do not meet a local, but a general, want. Whether a chillie crop is more profitable, I am not quite sure, for it must be borne in mind that chillie cultivation is garden cultivation, which for its success requires that the soil be constantly hoed and kept free from weeds. This means the expenditure of a vast amount of labour and energy constantly, of which the average Sinhalese is incapable of or averse to, unless stimulated by the prospect of a daily wage, when it will be found not to pay. Every one will be inclined to agree with the writer of the essay that if a proprietor has the capital (I am inclined to add to capital, Will and Energy, for we see capital by itself never used aright), he can put his land to more profitable use than to give it to goiyas. Croton and arnatto are suggested. The former yields a

* Will not placing coconuts on their sides in the nursery be a departure from the well-beaten track of experience? Yet it would be wise to try it on a small scale. The failure of 90 per cent would be conclusive against the experiment, assuming that the nuts were well ripe, and that silt washed down a slope is as useful as fresh soil. Again, may not the position of the nursery have given it too much moisture? We wish coconut planters more often published their experiences for the common good.—ED. "EX."

very powerful purgative oil used in very small doses and in exceptional cases. Increased supply will bring down the present high prices. As for arnatto, the cost of detaching the seed from the outer covering is very large and will swallow a large portion of the profit.

Amongst the enemies of the coconut tree, the wild pig has the first place. Not only because he is the most destructive to a young plantation I suppose, but because he is about the earliest enemy the plant has to contend against. White ants come next, and their ravages are simultaneous with those of pigs. Arsenic is said to be the best preventative, and the difficulty of applying it in minute doses is supposed to be overcome by filling a tub with water and adding a quarter pound sugar and two grains arsenic for every gallon of water, and flour sufficient to make the mixture assume the consistency of whitewash. Each plant is to be dipped in the mixture, it, being stirred the while, and left in the sun for the outer coating to dry. The white ant, it is believed, cannot get at the nut without partaking the arsenic. It is here assumed that the coating of the mixture will resist the action of water, for, be it remembered, that planting usually is done in the S. W. rains. If arsenic be soluble in water, I am inclined to think the mixture will be more effective without the sugar and flour, and if the plants, *i.e.*, the husk, be allowed to imbibe a portion of the mixture. I have heard alum mentioned as a specific for white ants. If the plants are allowed to imbibe alum and water with a dash of kerosine it may be good. To those with coconut plantations on the sea-borde, I would suggest the trial of a plan of a neighbour of mine. He filled a tub with sea-water and dipped his plants in it for twelve hours I believe. The remedy has the merit of possessing manurial value as well. Cattle, as an enemy, comes next in order, and is, I think, as destructive as any enemy, when it pulls out the toothsome cabbage or heart of the plant for a dainty mouthful. There is an end of the plant after that. Black beetle come next, but it is, I believe, seldom or never that a plant succumbs to its attack. It is usually fished out with a barbed wire; but for its extermination the heroic remedy of hunting every "dunghill, every accumulation of decayed vegetable matter or rotten tree" is suggested. This will involve a never-ending, and therefore very expensive, hunt, with very dubious results. The last and least in size, though not in its destructive powers, comes the red bettle. It is placed last on the list because it is perhaps the enemy of the mature more than the young tree. It is said to have no alimentary apparatus in its perfect state, its sole business then being propagation. It deposits its eggs wherever it finds a slit in the stem of the coconut tree. The resulting grubs work their way into the heart of the tree. This work of destruction done, and when the term of existence as a grub is drawing to a close, they withdraw near the rind and envelope themselves in a cocoon made of that part of the tree they have destroyed, and await transformation. We are told that the coconut tree is in danger of this enemy from the time it perfects a stem till it commences to bear, although I have had trees attacked long after they have commenced to bear fruit and yield crops. The cause generally is traced to the desire of planters to trim their trees to give them a decent appearance. This necessitates the pulling-off of all decayed branches and the exposure of the tender stem to the sun, which causes it to split, and there the beetle lays its eggs. Occasionally a tree is said to be lost from an accidental wound or a defect in the arrangement of its leaves. Observation has inclined me to the belief that the beetle does not, as a rule, go from tree to tree seeking an accidental wound or a slit in the tender stem where it may lay its eggs. If such a spot be found, it will no doubt be readily used by the beetle as a depository for its eggs, and save itself the trouble of forming one, which it invariably does. There is no remedy, we are told, for an attacked tree but to destroy it with fire. This is generally true, but occasionally a tree can be saved by cutting out a hole in the hollowed part of the tree, scooping out what has been destroyed with all the grubs and beetles it contains, and burning in the hollowed part any substance that will give a dense smoke. Immediately after, fill up the hollow with ant-hill earth and ashes saturated with kerosine and water or carbolic and water. Even this remedy fails except at rare intervals, but the vitality of the tree is impaired after the attack. I regard the red beetle as the most formidable foe of the coconut planter, and as destructive as all the other enemies put together. Means may be devised to circumvent the other enemies of the tree, as they carry on their work of destruction openly to a great extent; but the attacks of the red beetle are insidious, and very often the first intimation of its attacks is the droopping head of your very best tree. The attacks of the other enemies of the coconut tree are in their early life, when the loss can be easily repaired by a supply; but this foe attacks a tree after it has escaped every other foe, and about the time you expect to reap the fruits of your labour and patient waiting. You cannot avoid its attacks; but I remember reading sometime back that a pound of salt placed between the topmost branches of a tree, just before the two rainy seasons of the year, is a specific, as the melting salt forms a crust on the stem specially distasteful to the beetles. Now we know that salt dissolves even without coming into contact with water, so that so highly soluble a substance is not at all likely to form a rain-resisting crust even of a few months' duration. The benefit of the application to me is more imaginary than real. I will notice the second part of the essay in another communication.

After a long interval I resume notice of the second part of the Essay on Coconut Cultivation which appeared in the *Tropical Agriculturist* for July. Before proceeding, I cannot but refer to your foot-note to that part of my previous communication bearing on coconut nurseries. Nine out of every ten natives put down their seed coconuts on their side, and very often the tenth one too does it. The system has advanced a great deal beyond the experimental stage, and does away with the necessity for trying it on a few coconuts as you suggest, and the benefits of the system are not theoretical but real.* In detailing the advantages of putting coconuts on their side in the nursery, I forgot to mention that it allows of the resulting plants being steadied when planted out, by two pegs put crosswise over it, to overcome the displacement which follows the coconut holes being filled with water.

To resume. The "gratitude of the coconut for fertilizing matter" is exemplified by the robust and green appearance of the trees in the vicinity of habitations. The native accounts for this by the love of the tree for the human voice, and not, we are told, by the manure deposited by the family and their domestic animals. The writer thinks that the lesson to be drawn from this is, that we ought to hasten the profitable period by artificial means. To my mind this is a short-sighted policy. The lesson I learn from the vigorous growth of trees near human habitations is the benefit of keeping a plantation already in bearing in good heart to secure remunerative returns.

The usual or Goiya system of opening up a plantation is next discussed. The clearing of the land is done without any money expenditure by the proprietor; and in a favourable case, we are told, the land share of the secondary crop covers the cost of lining, holing and planting. I suppose this includes cost of plants as well, as it is said this system gives the owner his land planted free of all cost, except the purchase money and the interest on it. The plantation is then allowed to run into jungle for three years, "when there is the alternative of clearing the jungle or letting it grow on, and finally smother 90 per cent of the plants, whereas if cleared in the sixth year 50 per cent will probably be saved." A little complicated this, for we are not told what percentage of plants can be saved by clearing in the third year, nor is the period of time in the expression "grown on" indicated. The exactitude with which the percentages of saved plants by clearing at certain intervals is given, is, I am afraid, not the result of any calculation. In the twelfth or thirteenth year, when the more forward trees begin to bear, the final clearing takes place. By the second period of neglect 10 per cent more of the plants are lost. Of the 40 per cent alive, 10 per

* From the absence of any reference in his last letter to the planting of coconuts on their sides being practised by natives, we thought our correspondent spoke of experiments initiated by himself, but on enquiry the very next day, we found that the practice was very common in the country, and we mentioned the fact in a subsequent issue.—ED. "EX."

cent will be in bearing, and "the remainder of all ages downwards"—whatever that may mean. Mark, again, the certainty with which percentages are given, without even the small qualifying word "about." The annual expense of weeding and supplying is given at R12 per acre, and only about the twentieth year will the yield cover this truly moderate cost of upkeep, and even then 10 per cent of vacancies "*will*" exist. "Thus the cost of bringing coconut into bearing in the most slovenly and desultory manner will be R120, R30 of which will be recouped by produce up to the twentieth year." I fail to draw the same conclusion from the figures given.

The "effects of Lantana" are noticed next, and we are told that the above conclusions and figures hold good only if the land is of average quality, and the jungle to be encountered indigenous; but if the Lantana has crept into it at the third year, and is not cleared for three years, not one coconut plant will be left at the seventh year. It would have been useful to have been told what percentage of plants would have been saved if the Lantana had been cleared at the sixth, instead of the seventh, year. I wonder if the experience and observation of planters accord with the deadly powers given to Lantana, and with the statement that "the presence of Lantana in a clearing guarantees the extermination of every other member of the vegetable kingdom that depends on the first eight feet of space (?) for its air, light and sunshine." This statement, which everybody who goes about with his eyes open, can refute, stamps the writer as a person of very limited observation. I have known coconut plants allowed to be overgrown with Lantana soon after planting, cleared, not after three years, but after seven or eight years. To the surprise of the manager of the estate, he found a large number of the trees with flower spathes and commencing to bear, and not the deplorable sight of all the plants gone.

"Calculations of proceeds" I shall produce in their integrity, as the writer assures us that they give the history of more than one property under his observation during their whole life. "The average yield of average soil under the usual Goiya system will be 1,000 per acre—R30. There is R90 to make good, the interest on which at 10 per cent is R9; the current expenditure is R12, and there is R9 over to be deducted if we value the proceeds at R30. Supposing the annual increase of proceeds to be R5, it will take five years to rub out the R90 that stood at debit in the twentieth year. Thus, in the twenty-fifth year, the place is clear, and the annual average income will thenceforth be R38 per acre, as long as the price keeps up at at R30 the 1,000, and this calculation drops all the back interest in the original cost, as well as on current expenditure; from the twelfth to the twentieth year, which, if taken into account, would leave from R60 to R70 to be made up before the property was clear of debt." The island boasts of a few financial experts. It will take the best man of these to correctly solve and tabulate the above very complicated problem. Unprofessionals like myself will, in sheer desperation, feel inclined for suicide or to run *amok*.—*Cor.* "Examiner."

CANNING ORANGES.—By a process similar to that used for preserving other fruits, oranges have recently been successfully canned and shipped. The fruit is peeled, and broken into its natural sections, before canning, and when taken out is just ready for use. This is likely to become an important industry in the orange-growing districts of California and Florida.—*Popular Science News.*

COAL TAR.—"O. E.," Philadelphia, says:—"'At a recent meeting of the Montgomery county, O., Society, Mr. H. C. Smith stated that pitch tar was found to be more dangerous than coal tar to keep insects from injuring the bark of trees. This is very important information, as the general belief has been the reverse.' This is from the *Gardeners' Monthly*, March, 1882, but it does not elucidate the matter clearly. Can you throw more light on it?" [We called attention to the matter at the time merely as information, but have learned nothing further since. It was at one time recommended that a little coal tar should be painted around fruit trees at the collar, as a sure means of keeping out borers and preventing mice and rabbits from barking them. We had seen coal tar so employed serving the purpose admirably, and not injuring the trees in the slightest degree. Then came reports that trees had been injured, and it was surmised that some coal tar had too much creosote in it, which is known to be injurious to vegetation, and it was believed that pine tar would be free from this objection. It would be well worth while for any who may have had experience to tell what they know about it. There have been some very successful experiments of late made by using tar water against green fly and other insects, but we do not know anything from our own experience. Tar in most of its forms is liable to be injurious to vegetation, but in skilful hands it ought to be of very great value.—ED. G. M.]—*Gardeners' Monthly.*

CALAMANDER WOOD (*vide Tropical Agriculturist*, Vol. III., p. 717).—I apprehend that Calamander and Coromandel Wood are not one and the same, but quite distinct. The first, which by the Sinhalese is called Columedrya, and has been said, perhaps with reason, to be the most beautiful wood in the world, has, I believe, never been plentiful, and it seems now to be impossible to procure pieces of any considerable size. Some years ago I took much trouble, with the help of friends in Ceylon, to procure some, but without success; a few years later a consignment was sent to England: I saw this in the docks, and I do not think that the heart-wood of any stick was more than 3 to 4 inches in diameter. Such small pieces are of very little use, for they do not display the peculiar beauty of the wood, which consists in the great range of colour, from a light brown to black, displayed in a large figure or pattern. This figure is not seen to advantage unless the breadth of the wood is a foot or more. There is also in Ceylon a wood somewhat resembling Calamander, but much less beautiful—it is known as false Calamander; also one known as "flowered Ebony," black and brown in a small rather stringy pattern; the native name is Weiraneerruwelli. Coromandel wood (at least, that wood much used in the making of dressing-cases, &c., and so-called in the shops), is a wood of dark colour, nearly black, interspersed with many small irregular patches and lines of brown; it is wholly different in appearance to any of the three Sinhalese woods mentioned above. It is, I presume, pretty plentiful, and I suppose is brought from the Coromandel Coast.—ALEX. NESBITT.—*Gardeners' Chronicle.*

INDIARUBBER AND OTHER PRODUCTS IN GUATEMALA.—The preservation and extension of the cultivation of economic plants is a subject of so much importance at the present time, when so much is being done to promote new industries, to bring to light new sources of produce, and to develope those already known, that it is satisfactory to learn, from Mr. Consul Bennett's report on the trade and commerce of Guatemala during 1883, that the vexed question of tapping the trees, or cutting them down, was under discussion. What happened with the Gutta-percha trees (Dichopsis gutta) in Singapore and Penang forty years ago, by which the plants became well-nigh exterminated in those islands, has since been enacted in other countries with other useful plants. The Guatemala Rubber tree (Castilloa elastica) is a valuable source of this important substance, and should be carefully preserved. Consul Bennett says those in favour of cutting down allege that the quantity of rubber extracted by so doing is only equal to what would be collected in five or six tappings, after which the tree would die, and consequently that the yield, being immediate and of equal quantity with what would be given by a series of yearly tappings, and the tree in both cases dying, it is more to the interest of all to cut the tree down at once. This course, however, is forbidden by a Government decree. It is possible the law may be rescinded, and the practice allowed, on condition of two new rubber trees being planted for every one cut down. Guatemala is described as being rich in textile plants, Cotton, Ramie or China grass, Hemp, and numerous others. The native Indians are fairly skilled workers in cloth and woollen goods, somewhat oriental in character, and yet with both the material, the skill, and the labour on the ground, empty coffee sacks to the value of 40,000 dols. are annually sent to the Republic alone, mostly from Dundee. Ramie especially grows well, with an exceedingly long silky fibre, quite 24 inches in length, and in certain districts will produce four crops a year. It is not, however, cultivated or gathered, and remains only a unit in the long list of Guatemalan agricultural products, which are waiting for the master hand to turn their riches to account.—*Gardeners' Chronicle.*

ENEMIES OF TEA AND COCOA: THE LATEST ABOUT *HELOPELTIS ANTONII* IN JAVA.

We have received from Mr. Van Romunde, Mr. Moens' *locum tenens*, the Report on the Java Cinchona Plantations for 1883. It is in course of translation and will be published in an early issue. Pending the appearance of the full report, we give a translation of the portion which refers to the injuries effected by *Helopeltis Antonii* and the ravages of a caterpillar. In regard to both, there seems to be but one remedy, the constant search for, capture and destruction of the pestiferous insects. We must keep this in view in Ceylon, should the insect blight spread, not forgetting, as a source of encouragement, the intermittent character of the plague. Some years it entirely or almost entirely disappears. As absence of body is better than presence of mind when a railway accident occurs, we should prefer the absence of *Helopeltis* to any amount of knowledge of remedies; but, as the blight *is* here on cacao, and *may* spread to tea, it is so far comforting to learn that in Java measures of repression have been to a great extent effectual We append the extract from Mr. Van Romunde's Report :—

In consequence of the ravages of *Helopeltis* at Tirtasari the growth of the trees was seriously retarded, and therefore the measurements did not give the results which should have been looked for in the case of a normal growth. Among the unaffected trees outside the plantation chosen for measurement there were many stems of four years old which had reached a height of more than 5 meters. Considerable damage was caused during 1883 also by *Helopeltis Antonii*. The plantation of grafts and cuttings at Tirtasari especially had to suffer severe attacks. Strict orders were given to continue the pursuit of the insect unceasingly. By the end of the year the plants had completely recovered, only slight signs of sickness being noticed sporadically, and only at Rioeng-goenoeng were a few affected trees to be found in the Ledgeriana plantations. As a result of the stringently continued pursuit of the insect, it may with confidence be hoped that any considerable damage caused by the *Helopeltis* is a thing of the past. At Lembang considerable damage was caused to the Josephiana plants by caterpillars. Whole plantations were in a short space of time eaten entirely bare. In this case also the catching of the insect appeared to be the only method of cure. It was not always easy to reach the caterpillars in the already pretty high trees, and the catching was therefore not carried out so speedily as could be wished. Although the trees have to a large extent recovered from the injury done, yet the loss is very considerable.

JACKSON'S NEW TEA DRIER.

We recently gave a full description of this machine, and now we have received a copy of printed testimonials to its value, circulated by Messrs. Balmer, Lawrie & Co. of Calcutta and Messrs. John Walker & Co. of Colombo. Mr. Jas. Huttman, superintendent of Cinnamara, wrote to Mr. Jackson on 8th August :—

Your new self-feeding and discharging tea drying machine was erected here during first half of July and started working on or about the 16th of July. After 2 to 3 weeks experience of its working capabilities, I have pleasure in stating that I am perfectly satisfied with its powers of drying tea at rate of from $2\frac{3}{4}$ to 3 maunds of "Pucca" tea per hour; on several occasions the day's manufacture has been turned out at former rate, and now and again, or during half a day somewhat over 3 maunds per hour have been weighed off.

The expenditure of fire wood has been about 2 maunds of half dried wood per maund of tea which is not heavy, considering the green state of furnace and flues when works was commenced.

The internal arrangements of feeding hopper, travelling endless bands and discharging gear are very complete, and with ordinary care on part of workmen, are not likely to get out of order.

The principle of drying is an approved one, fresh pure air being admitted at one end of long cast iron pipes which are treated in furnace and flues, and air discharged at the other end at almost any temperature required, and drawn up through the tea by a powerful suction fan at top of apparatus.

The arrangements for lowering or increasing the temperatnre in machine are very simple and effective.

The number of coolies required to work the machine is reduced to a minimum, viz., one to stoke furnace, one to fill the feeding hopper, and one to carry away the discharged dry tea.

Other testimonials follow, and it is stated that

Mr. Jackson proposes to make *three* sizes, one capable of turning out 30 maunds per day, one from 15 to 20 maunds per day, and the remaining one from 5 to 8 maunds per day.

There is nothing yet as to prices. We suppose one of the merits of this machine is that tea cured in it will not be liable to so much breakage as where trays are used.

COCONUT OIL AND KEROSENE IN CEYLON.

Already the cheapness of kerosene oil from American wells has led to some very curious results even here in Ceylon. Not only in the towns, but in the remote villages, kerosene as a lighting material is rapidly superseding coconut oil. Following this is a larger quantity of oil available for export, which will enable the peoples of continental Europe to give a more satisfactory reply than they could in former days to the question "How are you off for soap?" A large proportion of the detergent substances they use have coconut oil for the base. We have several times referred to the enormous increase in the export of coconut oil in the season just closed, and we may add that there has been also a very considerable export to Europe of the raw material, copperah, from which oil is expressed by powerful machinery at certain places on the continent. Under ordinary circumstances, the export from Ceylon of coconut oil depends on the largeness or otherwise of the crop of coconuts. But this season the cheapness and increased use of kerosene oil have had their influence in producing the unprecedented figures. If the intelligence which has reached us in the London *Standard* of the 10th of Sept., as to immensely increased supplies of kerosene which Russia is able to pour into the markets of the world, from the wells on the border of the Caspian, should be confirmed, the time may be at hand when the vegetable oil which for centuries has supplied light to Sinhalese cottages and given brightness to religious processions and wedding feasts may be entirely superseded by a mineral oil from Pennsylvania or the Caspian Provinces of the Russian Empire. If only the example of the Caspian steamers is followed and the refuse petroleum used generally as steam-producing fuel, the revolution will be complete, and, amongst the most remarkable which has taken place in this century of change and of the old order giving place to the new. That discoveries of subterranean stores of so-called mineral oil (really derived from extinct organisms, especially coral insects), in America, in Russia, and we may soon add in Burma, should effect the displacement of coconut oil as a light-originator and lead to a supply of more and cheaper material for the manufacture of soap for use by, amongst others,

the former occupants of portions of Ceylon,—the Portuguese and Dutch,—are facts that surely go to the composition of a striking chapter in "the Romance of Commerce." We suppose many of us occasionally experience a fear that the earth's stores of fuel for man's use may give out. But if coal, the result of carbonized vegetable matter, becomes scarce, we have the products of fossil coral insects and fishes to fall back upon; and should these also be exhausted, we may feel assured that other compensating discoveries will be made.

INCREASING PRODUCTION OF CINCHONA BARK AND CHEAP QUININE:

FORTNIGHTLY AND HALF-YEARLY AVERAGE PRICES OF QUININE FOR 16 YEARS. THE NEED OF EXTENDING THE USE OF CINCHONA ALKALOIDS.

Among several inquiries induced by our letter on "The Planting Industries of Ceylon" in the London *Times* of the 26th August, there was one from a leading City firm in reference to Cinchona which led to a consultation as to the best means of making known the present exceptionally moderate price of quinine and the best mode of promoting an advance in consumption. At our request, a table showing the prices of quinine at the fortnightly sales in London for the past sixteen years was drawn up, but it did not reach us till the eve of embarkation. From Suez however we were enabled to send back a statement and appeal addressed to the London press with a summary of the figures which we give in full, on page 380, for the benefit of Ceylon planters and others interested in the important cinchona industry. The table of prices which has been prepared by a reliable authority shows that between 1868 and August last, the price of the most valuable of all febrifuges and tonics—Quinine—has never been so low as at the present time. This, of course, is partly owing to a temporary unsettlement of the market through the recent failure of the proprietors of the Milan Factory; but it is also undoubtedly due to the largely-increasing export of the raw product cinchona bark, from the East:—India Java, but more especially from Ceylon. The information we received some months ago in New York and Philadelphia from the leading Houses, one of which had a direct interest in a planting venture in Colombia, went to show that the South American cinchona bark is not likely to compete successfully any longer with the Eastern supplies to the London market. The margin for the profitable collection of natural bark is more than exhausted by the great fall in price, while several attempts at cultivation under American, German or local auspices did not give such promise of success as to encourage the extension of, or in some cases, perseverance with, the area already cleared and planted. A most striking testimony to the importance of our Eastern Industry is found in the fact that when the Guatemala Government recently desired to introduce cinchona cultivation in their hill districts, the President commissioned a Ceylon planter, then passing through the country, to proceed to the East Indies, procure a supply of the best seed and with that to commence an experimental plantation.

The English and Dutch Governments may well be congratulated on the rapid development of an industry which was originated entirely through official influence and in a very limited, inexpensive way, less than 25 years ago. To Mr. Clements Markham, above all others, is credit due for the introduction of cinchona cultivation into India, but the local Governments there as well as in Ceylon were fortunate in having agents so intelligent and earnest in carrying out the work as the late Mr. McIvor of the Nilgiris, Dr. King of Calcutta, Mr. Gammie of Sikkim (who besides cultivating plantations is manufacturing alkaloids from the bark for Government), and in Ceylon the late Dr. Thwaites and his successor Dr Trimen of the Botanic Gardens These gentlemen were encouraged at every turn by Sir Joseph Hooker and Mr. Thiselton Dyer of Kew; but we need scarcely say that they had great difficulty in persuading private planters to cultivate cinchonas—"medicine"—plants until the personal influence of Governor Sir William Gregory, between 1872-77, and the rapidly spreading blight in their coffee, forced plantation owners to turn their attention to "New Products." In Java the Dutch Government has been admirably served by Messrs. Moens and Van Romunde in charge of the cinchona gardens where most important work has been done in experimental cultivation and in the harvesting of the bark.

Briefly the result as regards the cultivation of plantations and the production of cinchona bark in the east may be summed up as follows:—

India began with an export of 26 992 lb. of bark in 1875 6. It rose to an export of 641,608 lb. in 1882-3 of which 400,000 lb. are reckoned from plantations in private hands. This is besides 350,000 lb. of bark used for the local manufacture of alkaloids in Bengal by the Government.

Java gave a crop of 200,000 lb. bark in 1878 and rose to an export of 904 970 lb. in 1882 (from Government plantations 506,000 lb and from private cultivation 398,970 lb.)

Ceylon began with an export of 28 ounces in 1869 and rose to an export of 6,925,595 lb. in season 1882-3; while for season 1883 4 a total export of about 11½ million lb. has been reached!

The area in cultivation may be given as follows:—

			[of trees.
India: Govt. plantations	3 300 acres	with 6½	million
Do. Private ,,	15 000 ,,	20	,,
Java (both) ,,	15,000 ,,	20	,,
Ceylon (all private) ,,	64,000 ,,	128	,,
Straits Settlements, Burmah, Borneo, North Australia, &c.	500 ,,	1	,,

The annual harvest of bark from these plantations was, last year, estimated roughly at 8½ million lb with the prospect of a steady rise, according as the demand afforded encouragement and the South American supply diminished; but seeing that Ceylon alone has given 11½ millions pounds of bark this season, the Eastern supply is already far outstripping the estimates. At the same time it is almost certain that, owing to the collapse of the Oriental Bank and the scarcity of capital, the Ceylon planters have been forced this year to strip off more of their bark than otherwise they would have done, so that the current season's shipments should show a considerable reduction on the export for 1883-84.

Though with a less area under cultivation than in India and Ceylon, Java is supposed to have richer bark, having a larger proportion of the valuable Ledgeriana trees growing on plantations. But this kind has also been freely planted in India and in Ceylon where every possible experiment in cultivation and harvesting cinchona bark, is being tried in order to discover the best mode of treating the trees. There is, we need scarcely say, a very great deal to learn yet as to the soil, climate mode of cultivation and treatment, calculated to give the best results.

Hitherto in many cases where the least attention has been bestowed by planters on their trees, the

largest profits have been obtained, as in the case of belts and boundaries planted with cinchonas as rapid growing ornamental trees before their marketable value was understood; while where plantations have been systematically and expensively cultivated, the result has too often been a failure.

Mistakes however are in a fair way to be rectified; and there can be no doubt of the permanent establishment of the Cinchona Industry in the three Eastern countries referred to, while experiments are being made chiefly under the direction of Ceylon planters in a variety of other quarters. It is therefore very evident that henceforward the East rather than the West is to be looked to for the world's supply of cinchona bark.

What is the result in reference to the supply of the alkaloids, extracted from the already increased crop of bark, so valuable to a large proportion of the population of the globe? This is the point to which attention has more particularly to be directed, the preceding remarks being merely by way of introduction to the question of Consumption It has been said that the degree of civilization attained by a country may be gauged by its consumption of sulphuric acid. With as much force we might refer to its "bill of health" as having a direct relation to its consumption of quinine and other cinchona alkaloids!

The importance of "bark" to certain countries can not be over-estimated, and no one can deny the truth of the statement by a Confederate officer that the final collapse of the armies of the Southern States was due more to the complete exhaustion of their supply of cinchona bark than to almost any other cause. In America the use and value of quinine is, in fact, much more generally understood than it is in England, and the consumption is large in proportion. It may be said that the malarious swampy plains common in the Southern States have no parallel in Britain; but we would beg to point out that, at least in the "Fen" districts, the people would be the better of a good deal more quinine or other cinchona bark alkaloids than they at present ever see. It is perhaps not generally known that, as a substitute, opium in the form of laudanum is largely consumed by people depressed with the effects of malaria or ague in lowlying districts in the Eastern counties of England, and we have heard that the quantity of this drug sold by apothecaries in the Fen districts and about Gravesend would rather astonish those who think that the use of opium is confined to the Chinese.

It is of special importance to point out the close relation between opium and quinine; how, in fact, the proper use of the one may be considered the remedy or preventive for the improper use of the other; and if, as seems likely, England, through India and Ceylon, is destined to give suffering millions in Asia, notably China relief through cheap quinine-philanthropists who denounce the opium iniquity may take comfort that compensation is in a fair way to come from the same Government. Cheap quinine would undoubtedly obviate the necessity for the use of opium over large districts in China where now the consumption is extending. We found that American missionaries in returning to China almost universally bring back packets of quinine pills for distribution as about the greatest material blessing they can bestow on the Chinese people under their care. It is most striking to learn from Mr. Colquhoun (in his "Across Chrysê"), how often, during his journey across Southern China, the question was put to him at remote stations:—"Have you any remedy for the taste (or craving) for the black smoke poison" (opium); and on this being answered in the negative,—"Have you quinine?" and how, again and again, mandarins and people valued a pinch of the febrifuge far more than his most striking gifts of Birmingham manufacture. We trust we have said enough to shew the importance to a large population all round the globe of cheap quinine: not only for human beings but for horses and cattle would preparations from cinchona bark be very beneficial if made available at a cheap rate. The great object now is to stimulate consumption in proportion to the prevalent moderate prices. It is possible that even medical men throughout the United Kingdom may not know the change which is coming over the cinchona bark trade. Certainly their patients and all sufferers from fever ought to learn the present position of the quinine market, because retailers of drugs have the habit of adhering to the old-fashioned prices long after such rates are out of all proportion to the wholesale quotations. Below, will be found the detailed return of prices to which we have referred: the abstract extending over the past sixteen years.

LANDING CHARGES ON TEA.

It may be of some interest to your planters to know, and I have taken some little trouble to procure, the landing charges upon tea and the percentage returned to the merchant at this end. The following table will clearly show the rates :—

	160 to 199 lb.	130 to 159 lb.	80 to 129 lb.	60 to 79 lb.	45 to 59 lb.	35 to 44 lb.	17 to 34 lb.	Not exceeding 16 lb.
	s. d.	s. d.	s. d.	s. d.	s. d.	s. d.	d.	d.
Landing and housing rate	3 6	2 7	2 1	1 9½	1 7	1 3	9½	5
Management rate	4 4	3 3	2 7	2 1	1 9½	1 4	10½	6
Bulking and taring	2 10	2 4	1 11	1 5	1 5	0 11	11	9
Rent per week	0 1	0 0¾	0 0½	0 0½	0 0½	0 0¾	0¾	0¼

Note that landing and housing rate is charged when goods are sold privately; management when goods are sold publicly. Both are not charged. The private warehouses have been gradually eating into the business of the London and St. Katherine Dock Co., by returning certain percentages to the merchant. The charges from full rates were reduced by this competition to 35 per cent allowed. Suddenly, and lately, the Dock Co., to put an end to further opposition and crush the private warehouses, are allowing 50 per cent; and the privateers, not to be outdone, have responded with 55 per cent. When this big leap was made, the private people tried to come to an arrangement with the Dock Co., against the common enemy, the planter, but all advances are so far made in vain. The Dock Co. are very bitter and are determined to maintain the low rates. I heard of one warehouse which last year showed a profit of £3,000 and is now barely covering expenses. Let planters take note, however, that at present they should receive back at least 50 per cent, and I will endeavour to advise any change.—*London Cor.*

THE CACAO (CHOCOLATE) PLANT AND ITS ENEMIES.

THE CEYLON PLANTERS' ASSOCIATION SUB-COMMITTEE'S REPORT ON THE CACAO PEST: THINGS NOT SO BAD AS THEY SEEMED—HELOPELTIS NOT THE ONLY SINNER: A REASSURING REPORT.

(*From the Proceedings of the Ceylon Planters' Association, October 6th, 1884.*)

Mr. ALEXANDER ROSS was called on by the Chairman to bring up the report of the Sub-Committee appointed at the last meeting to consider the question of cacao blight. He said :—Mr. Chairman and gentlemen,—I have pleasure in bringing forward the Report of the Sub-Committee on cacao blight, of which I was a member, and I can only say when you hear it read, it will be found to embrace the matter of the so-called insect pest, and that it is not in our opinion nearly so serious as it was at first supposed to be. We have passed through the most trying period of drought that I have seen in this

country during a residence of 22 years in Matale. The experience throughout that time has only emphasized the opinions we have expressed in this report, that the so-called blight is due mainly to local influences and local circumstances, want of shelter being the chief cause of the suffering of cacao.

The report was then read by the Secretary as follows :—

Report of the Sub-Committee of the Planters' Association of Ceylon appointed at a General Meeting held on the 28th June 1884, to take evidence and to report upon the cacao blight.

1. Your Sub-Committee have visited several estates in different districts with the hope of finding out the cause of the injury to our cacao trees in certain places recently. It has not been possible for us with the short time at our disposal to visit all the cacao estates or patches that have suffered, but we have seen enough to enable us to arrive at certain definite conclusions. We are convinced that upon careful examination the injury done may be referred to one or more of the causes we name.

2. Over well-defined areas in several districts we have found injury done to the cacao trees : the young shoots die and, in some instances, almost every new flush of young leaves is destroyed, and where this process is continued the older branches die back leaving in time only the stump ; this retains vitality, and under favorable circumstances will grow numerous suckers from which a new tree can be formed. We have heard of considerable areas being killed out entirely, but in our extensive observation we have seen comparatively few dead trees. That the injuries described are due to insects seems certain ; but whether to one or more, or what insect or insects, we are not in possession of sufficient evidence to say with certainty. This point, however, we consider of minor importance, as our belief is that under certain conditions the insects would not be numerous nor do any serious mischief. As certain meteorological conditions have a great influence on the increase of insect life, we are of opinion that the very abnormal season we are passing through has been unusually prolific in this respect and that the altered condition of the sap has rendered the trees more liable to the attacks of insects than they would be in normal seasons.

3. That the prolonged drought this season in most of the cacao districts amounting to an almost total failure of the south-west monsoon has had much to do with the damage is, we think, beyond dispute ; and we would even venture to say that but for this many of the estates that have suffered would have escaped almost entirely. This is borne out by the rapidity with which trees in fair soil have recovered after a few heavy showers of rain : trees that in May were a "ghastly sight" recovered so quickly that early in July two cacao planters went so far as to say the "blight" could never have been there ; this improvement has steadily progressed, and there have been no fresh attacks of insects or anything else. Another case in illustration. A small swamp, the soil of which is white quartz gravel with a little black mould, has about 20 trees four years old growing upon it ; deep drains were cut in it last year to drain off excess of moisture ; the trees have all withstood the drought, have lost none of their old leaves (their heads are so dense that they afford complete shelter to stems and the ground retarding evaporation), have had no insect attacks and have now a very good crop on them. On the other hand, those adjoining, in pretty much the same description of soil, suffered severely. The inference, we think, is plain : in one case, the trees had moisture and abundant nutriment which enabled them to resist both drought and insects, while, in the other, they suffered from starvation.

4. Speaking generally, we found that where the cacao trees were suffering severely they were without shelter they and the soil being exposed to the full force of the sun's fervid rays and to any wind that blew. We saw evidence in many instances of the plants having been at some period of their growth injured either at time of planting by clubbing of the roots or want of staking when growing or fallen trees and branches or sowing of the subsoil by checking of evaporation caused by excessive drought and consequent baking of the surface soil. In this connection we may mention that the late Dr. Thwaites was a strenuous advocate for mulching the soil, but as this cannot be done owing to risk from fire, the next best thing is to protect it by moderate shade overhead.

5. It cannot be denied that cacao has often been planted in places quite unfitted to grow it and in such cases we need not be surprized at failure. In free soil with good subsoil drainage, a year old cacao plant will have a tap-root of from two and a half to three feet long, and it will grow longer with the growth of the tree. Suppose a plant planted in ground with a foot or a foot and a half of good surface soil but with a hard and impenetrable or tough clay sub-soil, what would naturally result ; as soon as the tap-root reached this subsoil, it would turn aside seeking some crevice if possible, and, not finding it, would cease to grow downwards; it would have to depend upon this surface soil entirely, and perhaps in normal seasons would not for several years show signs of distress ; but on the occurrence of a drought it would naturally suffer long before the deep tap-rooted plant *even* felt it. It is a significant circumstance that cacao plants rarely die at the tips or are attacked by the insects that destroy the young shoots till after their second year, indicating that they have received a check which perhaps sickens them for a time.

6. We have been greatly impressed by the fact, that, wherever cacao has been planted in good soil with shelter and moderate shade and a suitable climate, there the injury is practically *nil* ; and we are convinced that under such conditions insects' attacks are not serious. Any ordinary drought at this season seems only to have the effect of retarding the formation of blossom and causing the shedding of a few of the more matured leaves ; this latter gives on superficial observation an appearance mistaken frequently for insect depredations, but the twigs and branches are after rain speedily reclad in verdure. The conviction forces itself upon us that those who discarded shade totally, ignoring the experiences of over half-a-century of our West India brother cacao planters, are now feeling the effects of their mistake, and the sooner we take a lesson from them on this head the better it will be—we mean of course light checkered shade where the sunlight can play through the branches and where the crowns do not meet.

7. There are numerous insects that live on the cacao plant, but few are yet known here that do much harm or whose depredations cannot be arrested. The one best known and most dreaded is the *Helopeltis Antonii* which causes such serious damage to the pods. Dr. Trimen tells us that he has taken the eggs from a gravid female and has also found them *in situ* in the young shoots and has seen the insect at work sucking the sap from a young shoot. All this proves that they breed in the shoots as well as on the pods, and may fairly be credited with a share of the harm done, but that they alone are responsible for the destruction of all the young flushes has yet to be established. Several descriptions of bugs and flies all armed with proboscees are found on cacao and are capable of doing mischief. *Thrips* have been very numerous this season in parts of the cacao districts, and may have contributed towards retarding the recovery of the trees.

8. The loss sustained by *Helopeltis* attacking the pods is often very serious, and measures should be adopted to minimize it. We have heard unslaked lime sprinkled on the young pods suggested, but against this there is the fact that the larvæ have lived and thriven under a dressing of unslaked lime and sulphur. Picking the insects off the pods will do good and keep down their numbers, and gathering periodically and burying all badly affected pods will destroy large numbers of eggs as it is known that the insects breed on the pods. The most effectual remedy, however, is by establishing a colony of the large red ants in each tree, for where they are the pods are always bright and free from spots.

9. What in Ceylon are known as the "Carácas" and "Forastero" Cacaos in all their varieties are far less delicate than the ordinary red one we usually grow, and are capable of resisting in a marked degree the combined influences of inferior soil and insects. That these cacaos raised from pure seed have ever been killed out or even seriously damaged we do not believe ; but where they have been hybridized by a cross with the common red, they are liable equally with the red and under similar circumstances to the attacks of insects.

10. From what we have stated in the foregoing remarks we deduce the following as necessary for the successful cultivation of cacao.

I.—Soil should be good, rich and deep, or good loose and gravelly, with free sub-soil drainage; good soil with large boulders and stones grows it well; surface drainage is necessary.

II.—Shelter is absolutely essential.

III.— Shade is advisable, but it should be grown with the cacao—not left in clearing the jungle.

IV.— Staking of the plants from the first to the third year where there is wind is of the greatest importance, as from want of this much mischief is caused, that shows in after years.

11. That the cacao "blight" is not nearly so serious as was at one time thought, is we think, proved, and, if the precautions as to shelter and shade are carried out we believe, that, wherever the soil is good and the rainfall sufficient; places now suffering will eventually recover. Quick-growing trees such as the different kinds of Erythrina should be planted through such places thicker than they are ultimately wanted so as to get up shelter and shade with as little delay as possible.

Plants from the seeds of the *Erythrina Indica* grow quickly and attain in one year a height of over 12 feet with about the same spread; cuttings also grow rapidly. Some prefer planting the cotton-tree which is a quick grower and can be raised from cuttings as well as seed, and also yields in a few years a valuable marketable commodity.

12. We would here tender our thanks to Dr. Trimen for so readily accompanying us in one of our visits and for the patience and courtesy extended in examining and reporting upon the numerous insects sent to him.

(Signed) WILLIAM JARDINE,
ALEX. ROSS.
For H. J. VOLLAR,
ALEX. ROSS.

ADVICE TO YOUNG CACAO PLANTERS.

(*Continued from page 333.*)

ROADS.—In cutting roads you ought to consider the best trace to connect your estate with the nearest main or road connected with main road; then carry on your road from entrance of estate to the store From this road you must select the best spot to cut a road for cart or hackery to take your raw produce to store, your manure over the estate and cured produce from store to nearest main road. After you have got a good road traced and cut, bearing in mind the above-mentioned points, then cut branch roads from the above road, so as to have easy access to all parts of the estate, bungalow and lines. An estate cart-road should not be steeper than one in twenty feet, though one in fifteen is useful when no better gradient can be got. It is well to have drains along all your roads, unless you give a good slope inwards to them and cut drains close above them.

DRAINS.—In draining an estate, your object must be to carry off superfluous rain-water into nearest ravine, if your ravines are sufficiently close; if not, you must make some cross-drains where distance of ravines is too great for drains to carry water to ravines. You should always do your drains after roads are cut. Eighteen inches deep and wide is always considered a good size drain, and, from thirty to fifty feet apart according the steepness of the land; the steeper the and the closer the drains, except when the soil is very wet or swampy even flat land must be close drained. There has been great mistakes made in making drains too steep with no large silt holes out in the drains whereby tons of soil have been lost to estates. I would make my drains of a gradient not steeper than one in thirty—with silt holes, say, four by four and six feet deep at sufficient distance, apart and as much as possible on ridges, as it is on ridges most soil is washed away; and the soil accumulating in these holes can be taken out, mixed with some manure and given to plants on ridges, when they are two-thirds full.

WATER HOLING.—It is well-known cacao likes lots of moisture. To retain rain-water on estate, cut long and deep trenches to all your plants, say, from four to eight feet long, eighteen inches wide and deep, these will also do for manure holes. Put in all your weeds, leaves, add some manure and soil now and then until your hole is near full; then make another either immediately above or on the side of the plant. I would not lose an inch of rain-water if I could help it, and, to stay evaporation of moisture from the trenches, I would always keep them full of light shrub, cut up plantain stalks or mana in the dry season. Plants will grow much faster with lots of rain-water, &c.

DISTANCE.—This will greatly depend on the quality of the land and shelter: in good rich soil well-sheltered, twenty to twenty-five feet apart; in poor soil or on ridges, a little windy, eight or even six feet apart. When lining, you should try and bring your lines a little closer on ridges and further apart in hollows even then your lines will come straight again, if properly looked to Cacao planted amongst Arabian coffee at fifteen feet apart will thrive well and not injure coffee, but both require to be well nourished.

SHADE AND SHELTER.—If you open new land, it is easy for you to select your shade trees or belts at proper distances as may be required. It is acknowledged by most planters in Ceylon as well as other countries that shade is necessary for cacao. I am aware there are some planters who say shelter is sufficient, and I hear there are some who actually say their best cacao is in the open. In the latter case, I can only say those trees must stand in land which must have a deep moist clayey subsoil, or, if you dig down some six or eight feet, you will find water. Wind-belts, as a rule, you cannot rely on. I have known wind-belts selected and left by very experienced planters prove a failure, as the wind somehow found an entrance in the magic circle and did more damage than if there was no belt at all. On the other hand, in hot dry weather you will find the heat concentrated within this belt so much greater (like Montclars system of retaining moisture with coffee, where the heat in dry weather caged up around the tree did more damage than the rain did good), that your cacao will most likely suffer. Further, you leave a hot-bed for all kinds of insects, rats, beetles, grub, &c. Besides, you ought to cut a deep trench all around the belt to prevent the jungle roots from taking the nourishment wanted for your cacao. Even if you will clear away all the underwood, plant a shrub, cinnamon, cardamoms or croton-oil under the large trees along boundary, you will not be as safe as when you have an even shade all through your cacao field. The next question is where you have old coffee land to plant up or land which was only lantana, shrub, mana or patana (there is some very good land for cacao of these descriptions), what is the best shade and how close is shade trees required. I have heard one experienced planter say, some of his best cacao is in dense shade and some very good cacao growing under Ceará rubber trees: some prefer one shade some another. I know shade trees of all descriptions, and find cacao doing well under near all the different trees—when too thick you can always thin out; if too many surface roots which injure your cacao cut them off. But, when you come to the most profitable tree, then the croton-oil tree stands prominent on account of its fruit; next comes the jak on account of fruit and timber hereafter, if you prevent the coolies from throwing the fruit on your cacao or don't allow the fruit to get to ripe on the trees and fall down of their own accord; then comes the *Erythrina umbrosa*, suriya, hog apple, rambutan, soursop, Malay apple, milila, nutmeg, &c. I believe the larger the variety of fruit and timber trees the better. A variety of fruit-trees will keep away squirrels and other insects from the cacao. Plantains as a temporary shade are very good and useful afterwards to be cut up in small pieces and put in your trenches

as a manure and for retaining moisture, and I would plant plantains along ravines to be cut up as required and given in trenches on the ridges.

(To be continued.)

PLANTING IN SOUTHERN INDIA:

SOUTH WYNAAD NOTES: COFFEE DEPRESSION AND PROSPECTS.

VYTHERY, Sept. 17th.—I see that the eminent politician, pork-pickler, and man of pleasure who represents Cavan in Parliament, has been asking Mr. Cross questions as to the disturbed state of this district, possibly with a view to transferring the energies which are cramped by the Crimes Act and the law regarding breach of promise, from Ireland to the west coast of India. From his reply Mr. Cross, too, seemed to think that we were in rather a bad way, but added that the Government had appealed to all classes to keep the peace. Perhaps it has done so, but in that case the planters were not considered a sufficiently important class to be included in the appeal, for the only notice Government has taken of any of us lately, has been to send us each a circular, signed by the officer in charge of the Wyuaad Survey party, (dated, need I say, from Ooty) to the effect that the demarcation of our estates, which we were recently compelled to ea ry out at considerable expense, will not be taken as establishing any evidence of claim to the land. Government, too, as you have doubtless heard, refuse to amend the law, so as to enable employers to proceed against maistries and coolies for the recovery of advanees in eases of breach of contract. Principally in consequenee of this refusal, and of the recent decisions of the High Court, with referenee to this law, one gentleman here has resigned the Honorary Magistracy, and has given his reasons for doing so in a letter to our Association, which would no doubt make Mr. Grant Duff "squirm" if he ever read the papers. Let us hope some of his colleagues may have their minds enlightened by it. This decision of Government affeets planters in other districts as much as ourselves, but I see that, in spite of it, the Coorg men are showing their effusive loyalty by trying to get up a Volunteer Corps. But I suppose the real object is not so much to get up a corps, as to get up the railway; and that as soon as twenty men have put down their names. we shall be told that in case of a disturbance, a railway would enable these heroes to move to the relief of the garrison at Cannanore. Let me just say, in reply to your correspondent "Shedwell," —who has been taken into the confidence of so many of the mighty ones of the earth that I did not understand the statement I spoke of, in my last letter, as having been made to the Association, to be an official one. It simply amounted to this, that a certain scheme of railway, extension had been sanctioned by the home authorities, and that a railway from Mysore to Wynaad and on to the coast, was included in it. What alterations circumstances may compel the Government to make in this scheme, before its completion twenty years hence, are probably only known to inspired creatures like Koot Hoomi and "Shedwell" himself.

It is rather late in the day to refer to the letter of "V. R." and "A. J. S" about the depressed state of the planting community; but, without entering at any length into the matter. I may say that the general opinion here is that "V. R." takes a far too gloomy view of things. In the first place, if he only got R600 per ton for his coffee last year, it must have been his own fault; for one firm on this coast offered R42·8 per cwt. (R850 per ton) last Dec., and several planters got as much as R40 per cwt. previous to this offer being made. I suppose that "V. R." (in company, I regret to say, with a good many others of us) thought he would do better by sending the coffee to the London market. If he failed to profit by his speculation he has only himself to blame. Again, as to not talking to him about cinchona, he is somewhat unreasonable. One company at Devala is reported to have sent home 40,000 lb. of bark lately, and to have realized an average of two shillings a pound for it, which would leave a very handsome profit, and the bark sold by Messrs. Oakes & Co. in Madras fetched 10 as. per pound. Besides this, while not agreeing with the sanguine estimate of 10 cwt. of coffee an acre made by "A. G. S." I certainly think that 3 cwt is far too low an average on any butquite worn-ont soil. The letter of a Coorg "Planter," which you published on the 13th instant, does not give very much assistance to the eontroversy. There is nothing in his letter specially worth controverting, except the astounding statement that cinchona is a good shade for coffee, it being well known to every planter who has tried the experiment, that coffee planted up with cinchona gradually goes back as the cinchona grows. Still, "Planter," in his somewhat feeble meanderings round the subject, does at last make one statement that will command general approval, and that is, that coffee land is unable to pay the tax on it just at present. If the Government would remit this tax for a year or two, a great lift would in many cases be given to struggling planters. We often read notices in the paper directing Collectors to remit the tax on land in years of scarcity, and it is difficult to see why this should not be done in our case. The rent paid on land held from Government, and not yet in cultivation, is also very high, going up to as much as R1·8 an acre, after some years. The authorities pay little attention to the representations of Planting Associations, but a little agitation on these two taxes would at least be a more useful and practical employment for Honorary Secretaries than raising Volunteer Corps and becoming objects of derision to every military officer sent up to inspect them. Possibly if it could be arranged with Madame Coulomb that the application for remission of the tax should fall on the Chief Secretary's head, through the same hole in the "Leaky Palace" that let the rain in on King Shando's or else on his feet when he is next standing on his head in front of the "shrine," more notice might be taken of it than if it arrived through the ordinary channel of the post.

The general prospects of the district for crop this year are, as a whole, fairly good. We had a heavy burst of the monsoon at the end of last month, which did some damage to the coffee trees, and blocked the ghaut road, but things are now all right again. With regard to the poetical appeal you recently gave us on the subject of reducing coolies' pay, I am glad to be able to inform the Board that the movement to cut the Chermers down from five annas to four annas a day has been a success; and the higher sum is only paid on a few estates, where the scarcity of Canarese labour, and the pressure of work make it absolutely necessary to keep up a large gang of coast coolies. I wont to assure your correspondent, the "Regular Attendant," that I am not the author of the letter which appeared last Saturday signed "Another Attendant." On the contrary, I agree with the first of these writers that the subject had best be left alone in this column.—*Madras Mail.*

COFFEE "A PASTIME FOR PRINCES":

THE MADRAS GOVERNMENT KICKING IT DOWNSTAIRS. GOLD MINES *vs.* RHEA FIBRE.

VAYTRI, September 27th.

Coffee planting in Southern India is rapidly approaching the stage to which the *Times* recently said keeping up a deer forest in the highlands of Scotland has already attained: it is becoming "a pastime for princes," a pretty enough amusement for a well-to-do duke, or a millionaire cotton lord; but as a means of making a livelihood it is getting a little played out. Ouida, who must find "the steam yacht at Cowes," "the villa at Monaco," "the lion-shooting box in Algeria," and the other usual adjuncts of a subaltern in the Guards (in her novels), getting somewhat stale, might add "a coffee estate in the Wynaad" to the numerous extravagances of her next hero. I can assure the eminent authoress, that as a means of getting rid of spare cash, 4 anna nap, which is the furthest I have gone in emulation of her brilliant creations, is a perfect fool to it. Our staple product remains at a hopelessly low price, and the *Madras Mail* is said to effect a considerable saving in its printing department by keeping Reuter's announcement, "M. P. Ceylon 63," permanently in type. As for cinchona, which we relied on to pull us through these bad times, it too has gone down to zero, because, people tell us, the bankruptcy of some big firm in Milan has thrown an enormous stock of bark on the market. If this bankruptcy had glutted the market with "old masters," or even barrel-organ-grinders, one could understand the phenomenon;

but its effect on the price of quinine can only be explained on the ground that the stars in their courses are fighting against the planters. In short, things are looking about as blue as they can.

The Madras Government, which has always managed to admirably dissemble its love for the coffee industry, is now going to take the next step and kick us downstairs altogether. It has already refused to make a slight alteration in the existing law of contracts, so as to enable us to proceed under it against defaulting coolies. I may mention, by the way, that it is only a quite recent decision of the High Court that informed us that we did not possess this right, after it had been exercised for 25 years; we might have survived this refusal, but Government have another attention in store for us. This is the revision of the Wynaad settlement, which is just about to be taken in hand. Nobody seems to know very much about the rights of the case, but it would appear that at the time when Tippoo was giving us trouble the Rajah of Cochin, who owned all the Wynaad, also uttered a wild shriek of liberty and had all his property promptly confiscated. The Nairs, who were his tenants, remained in possession, and as the district was considered to be an utterly worthless and fever-stricken jungle, they were left alone. When the planters came into the district they bought the land from the Nairs, giving in many cases very large sums for the freehold, or else paying down a smaller amount, and settling for an annual rental. Government stood by all these years and saw this going on, but if it now turns out that the Nairs had no right to dispose of the land, the planters are to be made tenants of the Crown, "on such terms as may be settled at the conclusion of the revision." And as to the sums paid for the land, we may recover them if we can from the Nairs, who will, of course, be utterly and irretrievably ruined. The only gleam of hope for us is, that as the Nairs will be even worse off than ourselves, someone in England is sure to make a fuss about it.

The gold mines which you heard so much of two years ago are nearly all gone to smash; the miners and the highly salaried managers have disappeared, and the only traces of them are the bungalows and adits that they lived and worked in. Some of the companies, whose capital is not entirely exhausted, are going into cultivation of rhea fibre and other products; their prospects of success are more or less doubtful, but the directors have adopted the motto of the railway ticket offices "No money returned," and the shareholders can "examine their change" at their leisure. I should mention, however, that the Balaghat mine in Mysore is said to have lately given an extraordinarily good out-turn, but their capital appears to be nearly gone, and a prospectus has been issued in the Madras papers offering a new issue of shares for sale. Whether they will be taken up or not remains to be seen. The crushing which raised the shareholders' hopes was little more than a trial one, and though money is said to be so cheap in England, the British public has had enough of gold-mining to last it a bit longer.—*Times of India.*

TEA IN AMERICA.

The hold which the Japanese had at one time on the American market has been weakened by the action of tea growers and importers who were indifferent to the quality of the teas supplied, and very reckless in regard to the colouring process and matter used in the manipulation. A good opportunity was thus offered for the introduction of Indian teas. Strange to say, the attempt recently made has not been vigorously pursued. The new York correspondent of the *Grocer* writing on August 14th says:—

"The steamship 'America,' which sailed from this port yesterday, carried Mr. K. Okura (of Okura and Co., Japan) and Mr. M. Yokohama, both of whom are members of the Nippon Seicha Kiokai, the first named being chairman of its governing committee. The organization is a commercial association of over a thousand tea producers and merchants. On the 6th inst. both gentlemen entertained at dinner, at Delmonico's, leading tea merchants of this city, the object being to make their acquaintance and gather information relative to the trade in Japan tea and silks. Mr. Okura is a man of fine personal appearance. Mr. Yokohama has spent three years in London, is an extensive traveller, and has a fine command of English. The total commerce of the United States with Japan is about £4,000,000 sterling, of which £3,000,000 is imports (90 per cent. of which are tea and silk), and exports of about £800,000, of which three fourths are petroleum, and the balance all manner of gimcracks.

"Since 1878 the imports from Japan have doubled, and the exports increased 50 per cent. The imports of tea amount to about 35,000,000 lb., representing nearly one-half the tea consumed here. I believe that England or English interests can reduce this, but it cannot be done without a sacrifice of a great deal of money, continuous hard work and a great deal of advertising. Can you tell the grocers of this country why immigrants accustomed to drinking blended teas, or congou, or souchong in their native country, abandon their use here? The truthis, our retail tea dealers know very little about blending teas, and have little disposition to learn. For a time, when the Calcutta Syndicate spent a good deal of hard cash in bringing Indian teas to the notice of the trade, an inquiry was started amongst grocers in regard to the best methods and formulæ for using them with other sorts. It bade fair to increase rapidly, and finally result in creating a good demand for India teas and such China sorts as congou and souchong.

"The cessation of work on the part of those interested in Indian teas has caused the interest awakened to die out. The custom is growing of giving presents to purchasers of tea. Those who do this and understand their business are giving their customers blended teas, and the result is—satisfied consumers, and the demoralization of nongift-giving dealers through loss of trade. Japan tea will lose favour with consumers in proportion as mixed teas of a high order are pushed upon their notice. The flavour of medium and low grade Japan tea is not agreeable. Originally when they were introduced, they became very popular, because the people were imbued with the notion that they were purer than China teas, and hence less injurious to health. They were free from colouring matter. Later, they began sending coloured teas here, and now again the demand for natural leaf is reasserting itself, and coloured teas are decidedly less popular than two or three years ago. It is claimed that basket-fired Japans lose their flavour much more rapidly than coloured teas. Then let the shipments come forward more gradually. From 1872 to 1877 a great deal of money was lost in the Japan tea trade, due to the importation of common tea and dust. It was asserted in 1879 that not more than 1,250,000 lb. out of a total import of 23,000,000 lb. was choice, and equal in style and flavour to the first lots received here in 1859, and which changed the demand from China to Japan teas.

"At one time the teas were so badly coloured that a disagreeable scum arose in the liquor, and hurt the sale of Japan teas so much that the excessive use of gypsum and Prussian blue was ordered to be stopped. That was in 1874, since which time less and less of objectionable matter has been used. These and other facts bearing upon the trade in Japan were presented to the Messrs. Okura and Yokohama by Mr. F. N. Barrett, of the *American Grocer*, at the dinner given by those gentlemen. His position was endorsed by Mr. F. B. Thurber. The latter gentleman made a capital speech upon the progress made by Japan, paying a high compliment to their shrewdness, wisdom, culture, and spirit of enterprize. There was a grand opportunity for the introduction of Indian teas in United States. He believed teas from China and Japan had had their day owing to the common and trashy kinds introduced."

If teas from China and Japan have had their day, it seems strange that the endeavour to popularize Indian tea should have collapsed just at a time when there was a prospect of some result. The Japanese are doing their best to maintain their position, and it seems extraordinary that those interested in the Indian tea industry should leave the field to them at a time when the chances in favour of Indian tea were good.—*Home and Colonial Mail.*

TEA ADVERTISEMENTS.

The following advertisements which appeared in the *Standard* are interesting, as showing the different lines on which the prevailing system of pushing tea is conducted. We omit the addresses of the vendors:—

THE PERFECTION OF FINE TEA.

Pure "China" Lapsang Souchong, of the same kind and quality that used to be imported many years ago, but now

so difficult to obtain. To connoisseurs of something really choice this is specially recommended, being quite free from any admixture of Indian or other teas. 4s pound.

TEAS.—Notwithstanding the Franco-Chinese war, and consequent rise in the Tea Market, we yet sell sound Congou at 1s per lb.; strong flavoury kinds, 1s 3d, 1s 6d, 1s 9d, 2s.

This system of advertising is thus criticized in *John Bull and his Isle*:—

"Every grocer—I might say without exception—displays the following announcement in his shop: 'When you have once tasted our tea, you will drink no other.' One of the largest tea-houses is not ashamed to publish the following advertisement in all the public thoroughfares and railway stations of England: 'We sell at three shillings a pound the same tea as we supply to dukes, marquises, earls, Barons, and the gentry of the country.' The poor viscounts are left out: it is a regrettable oversight."

Perhaps the candour of the man who tells the public that he sells China tea unmixed with "Indian or other teas" at 4s per pound is preferable to the duplicity of the dealer who professes to sell Indian but gives a cheap blend of China tea.—*Home and Colonial Mail.*

BRAZILIAN, OR MATE TEA.

Some effort is now being made to familiarize the British public with this Maté tea. At the Health Exhibition will be found many examples of Brazilian tea, the produce of the Brazilian holly (*Ilex Paraguayensis*). They may be recogeized by their dull yellowish colour, and by their being in small flat fragments of broken leaf, not curled or rolled as is the case with China tea. This Brazilian or Paraguay tea is used by millions of people in the New World, as the China tea is used by millions in the Old World. The holly from which it is derived is a free-growing, handsome shrub, with opposite ovate leaves, stout in texture, of a rich green colour, and bearing green colour, and bearing greenish flowers, which are four-parted. Although now to be met with in botanic gardens everywhere, there is a certain degree of interest attaching to the figure of it in B.M. 3992 (1843), although that was by no means the first figure published, for Lambert, Sprengel, and Sir W. Hooker had previously figured it. As a garden plant it requires warm greenhouse cultivation, but is in no way peculiar, so that whoever can secure a healthy plant may easily keep it. If grown in the same house with *Thea Bohea* it is quite at home, and has perhaps more interest for the observer than if grown apart from the tea plant of the Old World. The one point of interest for us here is as to the "table quality" of this tea plant. It offers us some peculiar advantageswhen regarded from the domestic economy point of view. It contains very little tannin, and therefore does not damage the digestive organs as China tea is likely to do. Moreover, this comparative absence of tannin allows of the Brazilian teapot being kept "on the heb" for any length of time without detriment to the tea, and in fact proves beneficial, for this tea is the better for a long brewing. And, again, this tea not only soothes and refreshes the frame and clears the mind, but it contains what may be called positive nutrition in the form of mucilage, which is only brought out by long standing —*Home and Colonial Mail.*

GOVERNMENT CENTRAL MUSEUM, MADRAS.

The following extracts are taken from Dr. Bidie's long and able report on the working of the Government Central Museum for 1883-84:—

CURRENT WORK.

The following are some of many subjects regarding which correspondence took place during the year. In fact, the public seem to regard the museum as a reserve depot of universal knowledge, and if the staff cannot always furnish the answers required, they try to put the enquirer on the track of the needed information:—

Cinchona Analyses.—As mentioned in last year's report a complete series of specimens of our species of cinchona, collected by me on the Government Plantations, was sent to the Pharmaceutical Society. During the year under review, Dr. B. Paul published analyses of the whole of these in the Journal of the Pharmaceutical Society, and his article was subsequently reproduced in G. O. Revenue Department, No. 407 of 1st April 1884. In May 1883, I had the pleasure of accompanying Dr. Trimen over the cinchona plantations, and his interesting and valuable report on the species cultivated in Nilgiris and suggestions regarding the industry have since been communicated to departments.

Cochineal.—The correspondence referred to last year resulted in the importation of cochineal insects from Algeria, which were handed to Mr. Grimes, the Superintendent of the Central Jail, Coimbatore. This gentleman devoted much care and ingenuity to the experiment, but unfortunately the whole of the insects died. It was suggested that the failure of this trial was possibly due to the insects having been weakened by their importation in the hot months, Government, therefore, resolved to give the experiment a further trial in the coming cold season, Mr. Grimes in the interval preparing a garden of the cactus plant on which the insects may feed.

Caoutchouc.—The Forest Department were directed to send further specimens for analysis of the elastic gum yielded by Carissa macrophylla, but none reached the Museum during the year.

Landolphia.—A plant put out at the foot of a Morinda tree in the Museum grounds has run up to near the top, but the stem is very slender, and does not appear as if it would yield much milk.

Fish Parasites.—In the earlier months of the year there was a sort of panic regarding fish, a rumour having got abroad that the sea fish sold in the bazaars were infested with parasites which rendered them dangerous as articles of food. On examination of a variety of species it was found that they did not contain any more parasites than healthy fish usually do, and that there was no risk attending the consumption of fish. To allay the public excitement, however, it was deemed advisable to submit specimens of the parasites to the authorities of the British Museum, and they confirmed the views as to their innocuous character. The parasites were all tape worms in the cystic stage, and of the eight species represented, two proved new to science.

Honey Bees of Southern India.—A large collection of these from the various districts was forwarded to the British Museum, where, through the kind intervention of Dr. Günther, they were identified by Mr. Kirby. From his notes it appears that the whole of the Madras honey bees belong to 4 species, and 3 varieties of the genus Apis. viz.:—

Apis Indica, Fabr.	Apis dorsata, Fabr.
Do floralis, Fabr.	do do var. testacea, Smith
Do nigrocincta, Smith	do do zonata, Guer.
Do nigrocincta, Var (?)	

Apis indica is, perhaps, the bee that is best known and most widely distributed, and its honey is good and wholesome.

Apis dorsata and its varieties are the rock bees so formidable on account of their irritable temper and dangerous sting. Their nests contain large quantities of very fine honey, which is collected by the jungle people. The pretty little "Mosquito bee" is Apis nigrocincta var.

Pearl Fisheries.—Owing to the failure of these valuable sources of revenue, Government resolved to submit the subject to scientific examination, and the Museum was directed to advise the officer deputed, as a preparatory step, to collect the necessary facts concerning the points to which his attention should be chiefly directed, Dr. Kelaart in 1857, and Mr. Holdsworth, in 1866-67, made a careful experimental enquiry into the whole question. Both these were well known and highly-trained naturalists, and it is understood that they made numerous important

additions to the scientific history of the pearl-oyster, but, unfortunately, no copies of their final reports exist in the Museum.

Erythroxylon Coca.—This plant is perfectly at home in the museum compound, growing in the ground and seeding freely. It could be grown to an extent in Madras. According to Bentley and Trimen's "Medicinal Plants," the total produce of coca in South America is probably not less than 40,000,000 lb., which estimating the value on an average at one shilling per pound (for the best qualities yield at least 5 shillings) in the countries in which it is produced, would represent a total value of £2,000,000. Should coca therefore even become any article of consumption in Europe, which is not unlikely, or in this country, its culture would probably be very remunerative.

CEYLON'S NEW PLANTING INDUSTRIES.

CACAO—TEA—RUBBER—CARDAMOMS—PEPPER—FIBRES.

There left Colombo in the P. & O. steamer "Malwa" for Hongkong and Yokohama a gentleman who, from his direct interest in a large extent of plantation property in Ceylon and the enterprize and confidence he has uniformly manifested in the outcome of "new products," has been as "a tower of strength" to a wide circle of friends and observers amidst the gloom of the prevalent depression of the past five or six years. We refer to Mr. R. S. Fraser of Kandenewera and Wariapolla, who has just gone on a short visit to Japan, and who has on several previous occasions made trips from Ceylon, to countries in the East and West, which have borne fruit for the benefit of agricultural industries in this colony. For ourselves we have ever found Mr. Fraser cheerful and confident about the future of Ceylon and its planting enterprize, and he has certainly afforded substantial proof of the faith that is in him by the extent of his investments in "new products." It will be remembered that Mr. Fraser visited Trinidad and British Guiana at the time when attention first began to be given to cacao planting in Ceylon. He gave us the benefit of his experience in a description of "Cacao Culture in Trinidad," which was made available for intending planters at this office, and he at once proceeded to devote a large portion of Wariapolla to this new product. The result has been, as he told us, most satisfactory, and, contrary to one high authority, Mr. Fraser is confident that the growth of cacao, age for age, on Wariapolla (and on some other places in Ceylon) is equal to the finest in the West Indies or South America. Mr. Fraser went all over the two plantations which are acknowledged to be the best in Trinidad, and while, of course, there is nothing in this island as yet to equal the older trees there, he is confident that for trees of ten years and under in age, Ceylon will bear off the palm even from the finest plantations in the West. Mr. Fraser has always been opposed to planting in cleared ground or cutting down shade. Contrary to the Report of the Sub-Committee of the Planters' Association, he believes that the natural shade of trees judiciously selected from the original forest is preferable to that of trees planted expressly as shade trees. He thinks the Ceylon planter ought to have followed the example in this respect of his brother in Trinidad where the cultivation has been carried on for a hundred years. The finest cacao trees he has seen in Ceylon are among a limited number on Sylvakande estate, but we gathered that on the Wariapolla clearings, grown under natural shade, none of the enemies experienced or threatened elsewhere have as yet been encountered; nor have the cacao "walks" suffered from drought, so that the crop during the coming season ought to be very satisfactory.

On the same plantation there are 100 acres planted with Rubber trees, are we were glad in the face of recent reports of this industry—rushed into at first as a perfect El Dorado—being abandoned in certain quarters, to find Mr. Fraser so well satisfied with the growth of his trees and with the prospects of a remunerative harvest in due time. "In due time": therein is found the explanation of a good deal of abandonment. Those who are in haste to be rich must look elsewhers than to Rubber. The tapping of trees for a remunerative collection of rubber at two or three years old as was at first anticipated, is all a mistake. The Ceará rubber tree, which flourishes so readily in Ceylon that it already threateus to run wild through the jungle, requires from seven to ten years of growth before it can be said to be fit to yield an abundant and profitable because continuous harvest. But that the cultivation will be remunerative to the planter who can wait so long, Mr. Fraser has not the slightest doubt. He has already been experimenting in the collection of rubber from very young (two years old) trees of his own, simply because these were on ground that had to be cleared to round off fields of tea; but his large extent of rubber trees on Wariapolla is not to be touched for several years yet. In the case of the two years' old trees, Mr. Fraser (with the help of Mr. Dobree's knife, of which he speaks highly and of another invention of his own) collected some splendid samples of rubber (now in the hands of Messrs. Geo. Steuart & Co., Colombo) as fine as any of the Ceará kind we have seen in the London market. Mr. Fraser's experience was that it required about 15 trees 2 years old to give a pound weight of dry rubber; the maximum from one tree being 10½ ounces in 14 days tapping. He thinks it important that the rubber should be dried in the dark. We have no doubt that the samples we inspected will secure a high valuation; but, of course, neither quality nor quantity can be taken as a test of what is expected from the trees on Wariapola when mature, four or five years hence. So confident is Mr. Fraser of this industry proving a success in Ceylon, that were he Governor he would be inclined to plant up waste Crown land with Ceará rubber (at a very little expense) to secure the greatly enhanced value such planted areas would realize if offered for sale a few years hence.

Kandenuwera has always been a prosperous coffee plantation and even now a good many thousands of bushels of the old staple are annually gathered, but the reserve of fine forest land has been wisely utilized for Tea and Cardamoms. Fifty acres under the latter product are in a most flourishing condition, blosseming, setting and fruiting in a manner that gives promise of a continuous crop, this time, sufficient to pay the annual expenditure on the whole estate! The estimate of 100 lb. an acre is already about realized, and there is no appearance of abatement in crop. From the other side of the planting districts in Rakwana, we have received an equally satisfactory account of a small cardamom clearing, the estimate of crop being at the rate of 200 lb. per acre for the season

Mr. R. S. Fraser was not one of the first to go into "Tea," though the experienced manager of Kandenuwara, Mr. Hugh Fraser, has been a pioneer with this product on his well-known Laggala property. On Kandenuwara there is however now some 300 acres of fine tea, the prospects of which are all that could be desired both as regards growth and the quality of the leaf. Indian planters who have visited the district have been loud in praise of the suitableness of Matale in climate, soil and lay of land for tea cultivation, and Mr. R. S. Fraser declares that during

his visit to the Darjiling tea plantations he saw nothing to equal the growth and promise in Matale and in several other Ceylon districts. He agrees that Tea even more than Ceará Rubber has found its habitat in Ceylon, being able to hold its own against the strongest of native plants on land where it may have had from neglect, to fight its way. This we found to be the case in Lower Amhagamuwa last year, where an abandoned coffee clearing was in the course of a few months simply snuffed out by the invasion of weeds and jungle plants, while an experimental patch of tea held its own against all comers. An old, shrewd and very experienced Ceylon planter—Mr. Alexander Greig, formerly of Rangala and Sabaragamuwa—who gained an intimate acquaintance with the tea plant after he exchanged a planting for a mercantile career and became the agent of the then well-known house of Messrs. C. Shand & Co. at Chittagong,—expressed to us in Scotland lately the doubt as to whether the Ceylon soil had sufficient staying qualities to support long-continued cropping with tea. He dreaded a falling-off in crop or in quality, although of course judicious manuring might postpone the evil day. More especially did Mr. Greig doubt the advantage of planting tea on land previously cropped with coffee. We had the benefit of the presence of another old planter and practical agriculturist, Mr. Arthur Sinclair, during this discussion and the *pro's* and *con's* were keenly argued in connection with the future of Ceylon, its splendid climate, transport and labour facilities for a tea enterprize. But it was of course impossible to adduce proof of what tea might be expected to do in the distant future. Since our return, however, we have learned one fact that ought to reassure Mr. Greig and strengthen the position of local tea planters who may be inclined to utilize land once cleared and planted with coffee. On a field of Barra estate, Rakwana, which had been cropped with coffee for some eighteen years, Mr. A. Greig in 1864-65 planted some China tea amongst the coffee. From time to time the leaf was manufactured and samples freely distributed, and we remember well in 1872 visiting the spot in company with Messrs. Donnan and Sinclair and admiring both the growth and product. Systematic cropping has certainly not been attended to onwards from that date, but for several years back the leaf has been plucked and the bushes not only yield but look as flourishing as if they were growing on virgin soil. In the case of tea much more than of coffee or cacao, we think there is reason to anticipate comparative permanence for cultivation even on our average Ceylon soil. A leaf crop is less trying to the soil than one of fruit, and our usually abundant rainfall, rich in ammonia, must play an important part.

Finally we have to call attention to the question of an industry in fibres to which as yet comparatively little interest has been paid in Ceylon. It will be seen from the letter which follows, that the General Fibre Company is determined to challenge attention to their famous "Death & Ellwood Machine" by competing at the approaching trials of fibre machinery under the auspices of the Indian Government. All we learned of this machine at home predisposed us to regard it as a decided success; but we find that in Ceylon its practical success is not considered to be settled. We are certainly aware that Mr. Campbell who had worked a machine here and pronounced the result to be unsatisfactory if not a failure, confessed at home, when he learned some more about the working, that he did so under an entire misapprehension. He had had less than the minimum fall of water prescribed, and he had fed his raw product at a wrong point to the machine, which made all the difference in the work. The proof of success is now the great demand which is setting in for machines and we saw the result at the Company's stores not in mere samples but in appreciable and even very large consignments of prepared fibres of different kinds. Unfortunately the London market for fibres generally had fallen, but the produce of *Sanseviera Zeylanica* (a free grower here) as prepared by this machine was so much prized that a very high rate up to £40 a ton was obtainable for it. We brought away samples of the "Moorva" twine; as it is called, made from the fibre of the *Sanseviera* as well as of Rhea taken from considerable consignments received from India. We trust our Ceylon planters are not going to allow their neighbours over the way to beat them in this direction any more than in other new products. We have ventured to call Ceylon a paradise for leaf-yielding trees, but surely the same may be said of it in respect of fibrous plants. Meantime, we shall watch with special interest the result of the machine trials in India ofwhich the "General Fibre Company," through our friend the Secretary, courteously apprises us.

RHEA FIBRE AND THE NEW MACHINES.

The General Fibre Company, Limited,

London, E.C. 19th Sept. 1884.

DEAR SIR,—We beg to inform you that our Engineer, Mr. W. E. Death (one of our Directors), left here for Calcutta on Wednesday last, the 17th instant, and will be present at the trials with fibre machinery, to be held by the Indian Government about the middle of October at Alipore (?) or Calcutta, where he will show our machine in operation, Mr. Death is due in Bombay on 14th October, and will at once proceed to Calcutta, where his address will be care of Messrs. King Hamilton & Co.—We remain, yours truly, For the General Fibre Company Limited,

L. G. DUFF-GRANT, *Secretary*,

TEA IN CEYLON AND CHINA.—The Japanese have not pleased us by picking quarrel with the Chinese in the midst of their fight with France, which is a difficult job enough without further complications. Why Japan should claim a sovereignty over the Loo Choo Islanders is inexplicable to every one; it is true some act of warfare was committed by the Japanese a few years ago against the Chinese vassal prince who ruled the island, but this does not constitute the rights now claimed. Japan has learnt much from the civilzat ion of Europe, and, we fear, has acquired this insight into the ways of a certain power especially (Russia), and more or less of all, that the time of another's difficulty is one's own opportunity. How England can keep out of the trouble we cannot see. We only contemplate one satisfactory point, namely, that we shall not run short of tea. India is nearly equal to all our requirements. Yet only a few years ago the idea was ridiculed that we should ever produce tea at Assam, or that it would flourish out of China. Now the pearl of India, Ceylon, is also turning its attention to the cultivation of tea as a way out of the troubles she is in from losses in almost all her former staple growths. Ceylon tea, an expert and authority tells us, is the most delicious in the whole world, and it has a fragrance of its own superior even to Chinese tea, and a strength equal to that of Indian. Out of evil here clearly some good is likely to come to us, and England stands a little in need of a bit of luck once more—golden days may return. It is pleasant, by-the-bye, to hear that Cyprus this year, owing to the splendid weather, finds itself in a most flourishing condition, and will give us proof that we have a valuable aquisition—a primrose the more to lay before the stone feet of the great and gone, who had forecast, which, after all, is the supreme quality of a statesman, and without which, as we see, they but sorrily blunder.—*Home News*.

AN ENEMY OF TEA.—A correspondent writes:—"I send some tea leaves with white bletches on, apparently eggs. Can you tell me what they are, and if a pest we need have any fear of? I have taken all the leaves that were affected off the tree. No tender leaves had any on, and it was only this one bud of an inferior jat" The eggs are those of a scale bug.

CINNAMON.—The average yield of an acre may be put down at a bale of 100 lb; and the ruling price being 34 cents per lb. out of which 16 cents must be paid for preparation, it will be seen that Cinnamon yields only about R18 per acre. Deducting cost of upkeep, the nett result to the proprietor is almost *nil*! Of course, there are estates whose yield is double of that indicated, and whose average prices—ranging from 1s. to 2s 2d. in the London Market—are more than double the local rate, which really represents the value of badly grown and badly prepared bark; but still it is tolerably certain that, except about a dozen estates—chiefly in the Negombo and Ekelle districts—the rest yield but very small profits, if any. The attempt, by combination, to reduce supplies, by ceasing to prepare chips and coarse bark which yield a minimum of profit, having failed, the present prices will result in much of the Cinnamon in the hands of small proprietors being snuffed out by neglect, or being wisely replaced by coconuts or paddy. A large number of plantations have been brought to the hammer within the last few years, and it is not unlikely that many more will follow; but the reduction of exports is not yet.—"Examiner."

FIBRES.—It is very fortunate for the sake of the experiment in Rhea fibre, that the Glenrock Company have plenty of capital to go upon; and we may rest assured that under the able management of Mr. J. W. Minchin, no expense or pains will be spared to render the experiment successful. From some figures we extract from the *Madras Weekly Mail*, it appears that £5 is considered sufficient for the upkeep: this we consider is much under the mark, we think £10 will be nearer. To yield what is expected of it, the Rhea must be highly cultivated; it will require much manure, as it is an exhausting crop; but as the market value is placed very low, at only £30 a ton, there is here a large margin to fall back upon. Dr. Forbes Watson estimates the process of cleaning to cost from £7 to £9 per ton. It is estimated that an acre will produce 10 cwt. of clean fibre per annum. This at £15 would not leave much margin for profit. Cultivation per acre £5, cleaning say £4, would leave but little for freight and other charges. Indeed, fibre to be profitable must give at least £30 an acre. This perhaps will yet be accomplished.—*S. I. Observer.*

COFFEE AND PEPPER.—Panwila, 27th Sept.—Once more (this is now the fifth year) I am able to invite one and all to come and see—for seeing is believing—the splendid coffee crops on this estate (Maria), though we had a dry season, some leaf-disease and bug very bad in patches: this is further proof what can be done by careful cultivation during these trying times—a stitch in time saves nine—that this system carried on on this estate is a safe one. I am also glad to say there is a fine cacao crop on the trees: in fact a lot of trees are bearing too heavily, but the trees are in good heart. These are also being carefully nourished same as coffee, and both thrive and bear well side by side. It is a pleasure to see also the crop on the large croton-oil trees and some of the pepper-vines, &c., &c. This is the time for new capitalists to come to Ceylon, to buy up good or abandoned estates: there are many estates which, through bad supervision, neglected or careless cultivation, want of funds, &c., are now for sale; these can be planted up again with new products, as subsoil is still good and be made paying estates: some have still good, coffee which can be worked up. Careful attention must be paid and actual wants supplied in time of need. Superintendents must be careful agriculturists, not simple overseers of work: then new products will pay.

THE GRANADA COCOA CROP amounting to 3,825,000 lb. is larger than that of the previous season. The increase is due to the cultivation of cocoa being in greater favour than that of sugar cane; which, owing to capitalists refusing to advance on crops that have ceased to be remunerative from over production, is dying out.—*S. I. Observer.*

TEA IN S. INDIA.—We hear that tea has attracted much notice in Wynaad. Owners in the Ouchterlony Valley are now making extensive additions to the area under tea. A block of tea cultivation on the Chembaly estate, adjoining the above property has a trial tea-plantation upon it of some 12 acres; the five years old trees, Assam Hybrid variety, are of magnificent growth; and both soil, situation and climate are well adapted for tea cultivation. In the Ouchterlony Valley, Captain Griffin's tea has already averaged 400 lb. an acre, the average price of which, was a year or so ago, 2s. 1d. is now 1s 3d.—*S. I. Observer.*

COFFEE-PLANTING IN CEYLON AND SOUTHERN INDIA.—The *South of India Observer* writes:—"We observe more letters in the *Mail* deploring the situation, and planters 'V. R.' and others seem to have but little hope of coffee. Why Ceylon planters should be cited as skilful cultivators puzzles us, have they not lamentably failed, though they were in possession of a climate superior to Wynaad or Coorg? There is one thing that should strike planters, that is, if the trees on a coffee estate have once yielded good crops why they should not do it again. The climate has not changed, the tree demands nourishment which it does not get, the result is, short crops and disease." The sneer at Ceylon planters is unmerited. A fair degree of success rewarded their efforts, as well as those of the brethren in Southern India, until the calamitous advent of the debilitating leaf-disease. Even after its appearance manures were liberally applied until many planters found that they were merely feeding the fungus.

THE HIGH CHARGES OF CALCUTTA AGENTS ON TEA are thus noticed in the *Pioneer*:—

There is a good story told of the London and North-Western Railway, that in one of their advertisements the printer had inadvertently dropped the letter "l," and that consequently consignees were requested to come forward and pay the "awful" charges on their goods, or they would be sold on their account and risk. We never see a Calcutta agent's account of his dealings with a tea garden without being reminded of this advertisement, for the whole vocabulary of forms of charge seems to have been exhausted therein. Commissions for buying the articles required on the garden, with probably trade discount for selling the tea, and for advancing money; charges for office allowance, for postage, for petties invariably figure therein, it seeming to be a cardinal axiom with some tea garden agents that the shareholders exist for them, and not they for the shareholders. It is an old saying that India is for the Civil Service, to which we would add, and the Civil Service for agency houses in Calcutta, who invite them to come confidingly into their little parlours and leave their savings with them, when they will deposit them so safely and securely in such a nice little thing in tea that their minds will be at rest for ever. It is strange what an attraction a tea garden has for a Bengal Civilian, or a Military man in civil employ; and how eagerly he rushes in to open out new concerns and add to the fat commissions of the Calcutta agents. "Blind unbelief is sure to err"; so says the hymn, but it is a very safe stand to take when the prospectus of a new Company finds its way into your hands. Of the 98 Companies quoted on the Stock Exchange here, 19 are at a premium, 13 are nominally at par, and 66 are at a discount; 43 are returned as having paid no dividend for 1883, and 5 have not advanced as yet to a dividend stage. It seems clear that if tea is to be cultivated successfully for the *shareholder*, some radical change must be made in the present system, but the subject is large enough for a special letter, and we will postpone its consideration for the present.

DECOCTION AND INFUSION OF CINCHONA BARK.

BY B. H. PAUL, PH.D.

On a previous occasion incidental reference was made to the relatively small quantity of alkaloid present in the infusion and decoction of cinchona bark as compared with that contained in the bark used in making those preparations, and as it seemed desirable to examine this subject more fully, I have carried out a series of experiments with a number of different kinds of cinchona bark.

Setting aside that official variety of bark, commonly known by the term "flat calisaya," as being practically a thing of the past, I have operated chiefly upon samples corresponding more or less with the other variety prescribed in the British Pharmacopœia for making infusion and decoction. Cinchona bark of this description is now abundant, but the very wide range of difference in the amount of alkaloids present in different samples constitutes a practical difficulty in the selection of a sample suitable for pharmaceutical purposes. Some of the unusually rich kinds, such as the Ledger bark of Java, Ceylon and British India, are too rare to be altogether fitting for this purpose, while, on the other hand, bark is often met with which is almost destitute of alkaloid, though presenting external characters that alone would recommend it for use. I have, therefore, in all cases operated with bark selected on the more accurate basis of analysis, the results of which are stated below:—

	1.	2.	3.	4.	5.	6.
Quinine...	4·62	1·02	4·38	4·18	5·50	3·46
Quinidine	—	—	—	—	·37	·11
Cinchonidine	·27	1·29	·28	0·64	—	·91
Cinchonine	·10	·68	·25	·30	·20	·34
Amorphous	·22	·60	·38	·40	·40	·44
	5·21	3·59	5·29	5·52	6·47	5·26

These figures sufficiently show the differences which obtain in regard to the amount and relative proportions of the alkaloids contained in cinchona bark, and the samples referred to above were chosen as well calculated to furnish the information required as to the representation of the medicinal properties of the drug by the decoction and infusion.

Decoction made according to the directions of the British Pharmacopœia, with the sample of bark No. 1, gave the results shown in the following table:—

	In 1 pint decoction. Grains.	Left in bark. Grains.	In 1¼ oz. original bark. Grains.
Quinine	3·11	21·89	25·30
Cinchonidine ...	·41	1·06	1·47
Cinchonine	·31	·23	·54
Amorphous	·41	·75	1·16
	4·54	23.93	28·47

With the bark No. 2, the results were as follows:—

	In 1 pint decoction. Grains.	Left in bark. Grains.	In 1¼ oz. original bark. Grains.
Quinine	1·05	4·50	5·56
Cinchonidine ...	1·79	5·31	7·10
Cinchonine	·76	2·94	3·70
Amorphous	·57	2·75	3·31
	4·17	15·50	19·67

No. 3 gave—

	In 1 pint decoction. Grains.	Left in bark. Grains.	In 1¼ oz. original bark. Grains.
Alkaloids	6·5	22·4	28·9

No. 4 gave—

	In 1 pint decoction. Grains.	Left in bark. Grains.	In 1¼ oz. original bark. Grains.
Alkaloids	10·3	19·89	30·19

No. 5 was a fine sample of Ledger bark from Java; it gave—

	In 1 pint decoction. Grains.	Left in bark. Grains.	In original bark 1¼ oz. Grains.
Alkaloids	15·5	19·9	35·4

No. 6 was a mixture of natural and renewed Crown bark grown in India; it gave—

	In 1 pint decoction. Grains.	Left in bark. Grains.	In original bark 1¼ oz. Grains.
Alkaloids	8·33	20·44	28·77

It will be evident from these data that in making decoction of bark only small proportions of the alkaloids present in the bark used are made available medicinally, much the greater portion being left in the residual bark. Consequently, the decoction is a very wasteful preparation as regards this portion of the medicinal value of cinchona bark. At the same time it must be mentioned that there is a further deviation from the natural proportions of the constituents of the drug, inasmuch as those which are readily soluble in water preponderate in the decoction as much as the alkaloids are deficient.

In this respect the defects of the decoction of bark resemble those previously pointed out as appertaining to the liquid extract made by the process directed in the British Pharmacopœia. The product obtained in either case is not a normal representation of the material from which it is made, but relatively the decoction is in this respect a better preparation than the liquid extract.

Infusions prepared, as the B. P. directs, from the samples of bark Nos. 4, 5 and 6 gave the following results:—

	Grains.	Grains.	Grains.
Alkaloid in 1 pint of infusion	9·50	12·86	6·08
Alkaloid in 1 oz. bark... ...	24·15	28·30	23·01
Alkaloid left in bark	14·65	15·44	16·93

When it is remembered that the bark used in the foregoing experiments was of a better description than that commonly taken for the preparation of infusion or decoction, it can easily be understood that these preparations are often inferior in medicinal efficacy, and that much uncertainty may attend their use. This is a defect which necessarily attaches to all galenical preparations, unless they are made with special regard to the composition of the materials employed and to the chemical features of the processes followed. Whether these points can be taken into account sufficientiy to remedy such defects, or whether the labour of doing so would exceed the advantage to be gained, I leave for the consideration of practical pharmacists. In any case it seems, from a common-sense point of view, desirable that the efficacy of medicinal preparations should not be left to chance in any degree, but regulated and rendered as far as possible uniform by precise knowledge of their composition.—*Pharmaceutical Journal.*

OIL FROM THE GRAPE-SEED is now used in Italy for illuminating purposes. As extracted at Modena, thirty-three pounds of grape-seed yield about thirteen quarts of oil, or about eighteen per cent. The seeds of the black grape yield more oil than the white varieties, and those of young vines are more prolific than old stocks. The color of the soil is golden yellow, and twenty-five per cent is lost in the process of purification.—*Independent Journal.*

STABLE MANURE.—Notwithstanding the teachings of many excellent persons that stable manure is the most costly of all fertilizers, it is today the most popular of all. Possibly it is one of those direct cases in which accidental advantages outweigh direct ones—in popular parlance, a case where the "longest way round is the shortest way there." Horses and men are often in need of something to do, and they can be put to work at manure hauling when there is nothing else needed. Again, the lightening of the soil by the decay of vegetable matter is a gain. In short, the value of manure is not wholly a question of chemistry. —*Gardeners' Monthly.*

GINGER CHAMPAGNE.—This refreshing and agreeable beverage is, according to a French recipe, made as follows:—Take sixty gallons of water; add forty pounds of ginger cut in small pieces, and gently boil for half an hour, carefully removing any froth that may arise. Cool the liquor as quickly as possible, and when at a blood-heat (100° F) add nine pounds of raisins chopped fine and the juice of six dozen oranges and six dozen lemons. Allow the liquid to ferment, and after standing a month it may be bottled in the usual manner. If desired, the ginger may be omitted, and the number of oranges increased to eighteen dozen.—*Popular Science News.*

HOW WEEDS DIMINISH CROPS.

A remarkable instance, says Sir J. B. Lawes in one of his letters, of the effect of weeds in reducing growth, is to be found in the experiments carried on by the Duke of Bedford at Woburn. In the second year of these experiments a change was made in the management, and the necessity of keeping the land free from weeds was not sufficiently recognised. The following was the annual produce of the same plots of land manured every year with the same artificial manures, consisting of potash, phosphate and nitrate of soda:—

1877	...	...	...	32	bushels per acre.
1878	...	...	...	14	„ „
1879	...	...	...	25	„ „
1880	...	...	...	24	„ „
1881	...	...	...	45	„ „
1882	..	...	...	33	„ „

In 1878, the year when the weeds prevailed, the artificial manures yielded one bushel per acre less than the plot which was left entirely without manure. But of late years the land has been kept scrupulously clean, and it is now, in fact, cleaner than my own land at Rothamsted. The Woburn soil possesses one great advantage over my own, from the fact that weeding can be carried on without injury when the land is wet. There can be no doubt, however, that the large produce which is obtained, both at Woburn and Rothamsted, as compared with the produce obtained by ordinary farming, is very much due to the absence of weeds. At Woburn seven unmanured crops of barley, grown in succession, have given an average of 27 bushels per acre. This is a product considerably in excess of what might have been expected from a soil which, although fairly rich for the first 9 inches from the surface, is very scanty and poor below that depth. In order to test the influence of weeds I allowed the wheat to shed its seed on about half an acre of land at the top of my experimental wheat field. The crop—which if cut would probably have yielded 16 bushels per acre—has therefore re-sown itself, and will have to contend to the best of its ability with any weeds which may spring up. In writing some time ago upon the dependence of the human race for their existence upon some annual plant bearing a cereal grain, I pointed out how very much the growth of such plants depended upon the care and attention of man; and I suggested that if a field of corn were left to its own resources it was quite possible that not one plant would be found in the field after four or five years. Time will show what will actually take place in the present case. From the appearance of the land, and the prevalence of couch grass and other weeds, I should think that the present crop would be a very small one indeed, and probably the last that would grow at all. The remainder of the field—now under its forty-first crop—looks exceedingly well.—*Leader.*

PINEAPPLE CULTIVATION IN QUEENSLAND.

Many of our small cultivators are losing an opportunity of employing their time and labour to advantage in neglecting the cultivation of this valuable fruit. It has the advantage of nearly every other in escaping the ravages of fruit-devouring pests; for in our experience we have never known anything but the opossum to meddle with it. Then, again, it enjoys another very great advantage over any other crop in luxuriating in what are considered to be poor and hungry soils; free sand, or a loam with sand predominating therein, being found the best for the pineapple. In comparison with other fruits, the pineapple is very easily grown, will bear carriage well without sustaining injury, and has exceedingly good keeping qualities, if fairly treated and not knocked about or bruised. Unfortunately too many growers lose all concern about the goods they market so soon as they have sold them, and handle fruit without sufficient care and almost as if they were stones. A check must be put upon this, for bruised fruit cannot be kept long, and will not preserve; so that buyers must protect themselves against the careless and selfish growers who will not study their customers' interests, as only such measures will suffice to bring them to their proper bearings.

To grow the pineapple well requires a free and light soil, and as near an approach to a tropical climate as possible. Frost is the enemy of the pineapple, and where frosts are the rule this fruit cannot be a success. Experience has shown that they thrive even in Southern Queensland anywhere near the coast; but anyone about to make a plantation should be careful to make it as high up on the hillside as possible, or at any rate above the frost level; for it is a well-known fact that frosts settle into the hollows, and the tops of the hills are free, showing that cold is subject to the laws of gravitation. Supposing the site to be chosen and the soil to be suitable, the next question is the labour, and it is generally a vexed one. All authorities say trench and manure for fruit of every kind; but unfortunately majorities are not ruled by authorities. Most people calculate when they have a few thousand plants to put in how they shall get them in their places quickest and at the least expense; imagining that there is nothing else worth considering. This is a mistake. The question to consider is—how to treat them so as to get the best returns. If we had £100 to invest, and one thing offering promised 10 per cent profit, and another 20 per cent or more, we should not hesitate in deciding for the latter. Why not employ the same sagacity and forethought in planting? It is passing strange that so few have wordly wisdom enough in such matters. An acre well done is better than two or more slummed; and the double quantity of land will always demand an extra amount of attention to keep it in any measure productive, while after the first the better worked land will not require half the cultivation, and at the same time will give fully double the weight of crop. Trenching is the item here insisted on. Land intended for pineapples or any other fruit should be broken up at least 20 in. or 24 in. deep; no other cultivation is worth anything in this climate. "But," says a lover of his ease, "what is the use of trenching sand or a light soil?" The use is to make it lighter and sweeter and more productive; and, whether an active imagination or good reasoning powers will enable a man to fathom the mystery or not, it is an established fact that trenching, even light soil or sand if naturally well drained, makes a very great difference in the productiveness of such land. Besides trenching, it will pay to use manure. Trenching affords the cultivator an opportunity to bury rubbish of all kinds in the soil to open and enrich the land, and gives him a great advantage in that of surpassing his neighbour who burns all the refuse vegetable matter that he makes, or which accumulates on his land. The cultivator should never burn a handful that he can bury; and the longer he adopts this plan the more will he see the benefit of it, and the more reason will he have for continuing it. Then trench and manure if you would succeed with pineapples. Manure of any kind will answer, bone-dust being excellent and wood ashes also.

In planting make the rows 8 ft. apart, and put the suckers 3 ft. apart in the rows. In two or three years the rows will be continuous, and the clear spaces between will furnish facilities for cleaning, cultivating, and gathering the crop which could not be profitably dispensed with. If the surface of the ground is not all covered, the soil below will be fully occupied with roots, which have nothing more than fair feeding ground. Planting so closely that every plant robs and starves its neighbour is not wise, particularly in a climate like this, where droughts are frequent and crops are lessened in consequence. A plantation of pines treated as above, trenched 2 ft. deep, and well manured, with the plants no closer than recommended, would hardly ever feel drought, but would bear heavily in any season. Returns of £100 per acre per annum would surely justify this. "But," it may be asked, "who ever dreams of making £100 a year from an acre of pineapples?" There is no dreaming about it, for those who know assert that £100 per acre per year is now being made out of them. A German near Brisbane pays £100 a year rent for five acres of pineapples and makes a good thing of it; and, instead of the supply being equal to the demand, two or three times the quantity at present grown could readily be disposed of to men who are trying to develop a trade for the preserved article in the markets of Europe, but cannot get a supply. No industry in the gardening or the planting line offers better inducements to the energetic cultivator than the cultivation of this popular fruit, and there is undoubtedly a fortune waiting for any man who will enter upon the growing of pineapples in a thoroughly efficient and business-like manner.—*Queenslander.*

SIR JOHN SINCLAIR, THE AGRICULTURIST TO WHOM INDIA IS INDEBTED FOR GUINEA GRASS, ETC.

(Communicated.)

In the annals of agriculture, tropical or otherwise, no name stands higher than that of Sir John Sinclair. What steam owes to Stephenson, chemistry to Liebig, the science of agriculture owes to Sir John Sinclair.

If he who makes "two blades of grass grow where only one grew before is a benefactor to his country," what is he who introduces the finest herbage to a country where nothing of the kind grew before?

Of all the proud ancestors of his "lordly line," there is not one who has left a name so worthy of being fondly cherished in the hearts of his countrymen as that of this northern laird. It is a long cry to Thurso Castle, where, in 1754, Sir John (to be) first saw the light, and, if we could for a moment realize the condition of Caithness at that time we would be better able to estimate the marvellous improvements introduced by him and which by and by changed the rude and rugged face of Scotland into one of the best cultivated countries in the world (making due allowance for climate).

When Sir John succeeded to his estate, it may be said to have been in a state of nature. Within its limits there was not a single tenant who possessed a cart, for the very good reason that not a foot of road existed. The ground was poorly cultivated on what was called the alternate ridge system, if system it can be called, which simply grew sufficient to keep the bodies and souls of the sparse population together. With no ordinary difficulties to contend with, in the shape of poverty and prejudices, Sir John succeeded by his dauntless energy and perseverance in successfully combating all opposition, how successfully, may be seen by comparing the condition of Caithness in 1810 with that of 1820, where the proportionate increase of population was greater than in any country in the British Empire, a population too of a very different type from what had previously inhabited it.

Enterprize, industry, morality and religion went hand in hand, while the soil exhibited as skilful management as the most celebrated districts of the south. Nor were the remarkable energies of Sir John confined to his own country. A cosmopolitan in the best sense of the term, he began early to look far abroad and devise schemes for the mutual benefit of Britain and her colonies, and, while looking to the East for the benefit of such seeds as might be grown or improved here, he was not unmindful of the teeming millions in India who suffer from periodical famines. It was chiefly to his thoughtful care that the potato was first cultivated in India, and, if it has not quite fulfilled all that was expected of it, I suspect its cultivation is still susceptible of great improvement. But by far the greatest boon India acquired through his agency was the introduction of GUINEA GRASS. In a Calcutta journal I find a letter dated from Hare Common, near London, December 2nd, 1814, in which Sir John says:—"Understanding that herbage was much wanted in our Indian possessions, I ventured to recommend the culture of *Lucerne* ("gram"?*) and *Guinea Grass*, and sent some seeds of each that the experiment might be fairly tried. The result has been most satisfactory. In a letter from the East India Company to the Marquis of Wellesley, dated March 12th, 1802, there is the following paragraph:—"We have perused the Proceedings of the Board of Superintendence referred to in your dispatches, and we are much pleased to observe, by those proceedings, that the Lucerne and Guinea Grass thrive in such a manner as to afford a reasonable prospect of their becoming an acquisition to the Bengal provinces that will prove invaluable." Upon this subject Mr. Arthur Young observes in his lecture on the advantages which have resulted from the establishment of a Board of Agriculture:—"Should the cultivation of these plants spread in the manner to be expected, they will prove of as great importance to India as ever clover and turnips have done to Britain, which would have been cheaply purchased (had purchase been necessary) at the price of a hundred millions sterling."

About this time, Sir John and Warren Hastings were in close correspondence; and there is something so exceedingly interesting and instructive in reading the letters of these noble old men (the one over 70, the other 82), that I need not apologize for making a few extracts.

Mr. Hastings writes under date 24th August 1814:—"The practices of the East are doubtless capable of improvement, and such as this kingdom might impart to them; but the only way to begin it, seems to me, to be the process of inquiry: that is, to ascertain what their practice is, and in what it is defective, considering at the same time the differences of soil and climate, the bodily powers of the cultivator, and of the cattle that he works with, and all other peculiarities, even to the local usages of the country in this art, be they good or bad. We should be sure we are right ourselves before we assume the office of reformers. For instance, the oxen of Bengal, in their present state, would not be able to force a Norfolk plough to the depth of an English furrow, and to effect it would put a Bengal ploughman to the utmost stretch of his might. It is possible, too, that the soil might not be meliorated by turning it to so great a depth. I do believe that the superiority of understanding evinced by some of our inventions in husbandry, as in your instance of the threshing machine, with the great assistance which this art has received from the sciences, and the same superiority so eminently displayed in all the other arts of life, might induce the more intelligent of these people to draw the same favourable conclusions with respect to our moral and religious doctrines, and with the more probable effect, if left to their own reflections." Sir John adds:—"Honorary Boards therefore ought to be established at each settlement in the East Indies, and each colony in the West to carry this plan of mutual aid into effect. They would not occasion any expense, and would, by a correspondence with the central office in London, conduct the whole operation under the sanction of Government to the benefit of all our colonial possessions. On the whole, the advantages which might be derived by an attention to these objects are certainly incalculable. They would promote the improvement of the British Islands; they would augment the prosperity of our West Indian possessions; and they would increase the happiness and contribute to secure the permanent dominion of our territorial possessions in the East, and all these advantages might be obtained at an expense comparatively insignificant."

Amongst the descendants of our doughty Norman invaders, few have stood out more prominently in history than the St. Clairs, but, as true benefactors to their adopted country, none will be so well remembered as *Sir John, the Agriculturist*, and his devoted daughter Catherine, who so long and so well acted the part of his amanuensis. As old age crept over him, he began to feel the rigour of his northern climate, was fain to seek a home a little further south, and purchased a villa in Richmond, Surrey, but he found he was too old to transplant, and within a year sold his English house and returned to die in dear old Edinburgh, surrounded by the associations of his brightest years. In passing along the Canongate the other day, now one of the most squalid thoroughfares in the City, the house in which Sir John so long resided was pointed out to me.

In the private walks of life, says a contemporary, and in the exercise of domestic virtues, Sir John was the per-

---

* No: here is information for "C. S." in reference to Lucerne and the genus to which it belongs:—

MEDICAGO.—The Medick genus; one of the *Papilionacea*, and distinguished by its more or less spirally twisted legume. The more important species are the following:—*M. sativa*, the Purple Medick, or Lucerne. This, though found apparently wild on the borders of fields, has doubtless escaped from cultivation; it is distinguished by its purple flowers and upright growth. Its herbage is green and succulent, and has the advantage of being early, on which account it has been highly extolled as an agricultural plant. It yields too rather abundant crops of green food in the year, of a quality highly relished by horses and cattle. *M. lupulina*, the Black Medick, or Nousuch, is at first sight so much like the yellow trefoils as to be generally known by farmers as the Hop trefoil, or Hop; it is, however, distinguished by its naked black legume. It is used in farming to mix with grasses and clovers for artificial or shifting pastures, in which it often assumes a luxuriance of growth well befitting it for this purpose. *M. maculata*, remarkable for its spirally-coiled prickly legumes, has, from the quantity of herbage which it grows, been recommended for cultivation as a green fodder plant; but it is scarcely equal to the former, while in hay the long prickles to its seed-vessels render it very objectionable. [J. B.]—*Treasury of Botany.*

sonification of a Christian gentleman, and, with fewer faults and frailties than most men, he set a noble example to the world of intellectual activity uniformly directed, from boyhood to old age, to the one great object he had in life, viz., what in modern days may be called altruism or the greatest good of the greatest number. C. S.

SERICULTURE IN AMERICA.

In the letters by our special correspondent to America reference has been made to the admirable system by which the various agricultural associations are consolidated for concentrated effort, by a plan of federation within the individual states, which are in turn knit together by organised communication with the central head at Washington. From the head of that department we have received his elaborate report upon the progress of silk culture throughout the Union for the year 1883, from which we gather that the most important organised effort for the promotion of silk culture which has come into the field since the date of the last report is the establishment of the California State Board of Silk Culture at San Francisco, by authority of the legislature of California. The first regular business meeting of this board was held on the 1st of June, 1883, when it was decided that a short address on some subject pertinent to silk culture should be delivered at every regular meeting of the board. The first address was delivered by Mr. W. B. Ewer, of the *Pacific Rural Press*, on the Progress of Silk Culture in the United States. The board voted to offer premiums to the amount of 150 dollars for the best silk cocoons raised in the State during the year 1883, as follows:—Five premiums, respectively, 50 dollars, 40 dollars, 30 dollars, 20 dollars, 10 dollars; the cocoons to be thoroughly dried and to be put in suitable boxes by the competitors, and to be sent to the next State fair in Sacramento for exhibition. Bulletin No. 1 was issued by the board on the 1st June, and gives a list of members and officers, times of meeting and objects of the board. This board recommends home culture, discouraging speculation, guarantees to purchase all the cocoons raised for that current year in California, and to have them reeled at the State reeling school; guarantees to supply the best grade of eggs for next year, and urges everyone not to raise any eggs for themselves, lest bad breeds become perpetuated; and gives advice as to the preparation of cocoons for reeling or for the market, and the detection and treatment of diseased worms.

California appears to excel every other state in the attention which it is paying to silk culture, as in addition to the Women's Silk Culture Association of California, and the California Silk Growers' Association, which are mentioned, minutes are given of the proceedings of the California Silk Culture Association, which is stated to be, although independent of the State Board of Silk Culture, acting in harmony with that board, and meeting in its rooms. Mrs. Theodore H. Hittell was president of the first-named society and corresponding secretary of the second last year, and is now the correspondiog secretary of the last-named. Mrs. Hittell also reports that the State legislature has voted to appropriate 10,000 dollars the coming year to the encouragement of the silk industry.

Reports from persons to whom eggs were sent from the Washington department in the early part of 1882 continued to come in throughout the new fiscal year. Many complaints were made of the lateness and coldness of the season, but this seems not to have interfered with the success of the experiments, except by occasioning the death by starvation of prematurely hatched worms. Eggs kept from hatching by being exposed to artificial cold in ice houses and the like yielded healthy worms, even after the eggs had become damp and mouldy. Nearly all the letters (about 1,000) received by the department relating to silk culture were inquiries for information, for the silk manual, for eggs, trees, slips, or seeds. All applications for trees, slips, or seeds were dealt with by the horticulturist. Some correspondents observed that a portion of the eggs which they procured by breeding hatched in the course of a fortnight or less after laying, while the remainder of the eggs did not hatch. Two or three of these correspondents raised a second brood of worms, and speak well of this brood, considering that it takes less time to grow and less care than the first brood. Mr. S. G. Stoney, of Charleston, raised a third brood, which spun in August, and he considered this the best crop of the three.

Correspondents who fed the worms once or twice a day seem to have succeeded as well as those who fed eight times a day; and those who dispensed with stoves as well as those who were particular about the temperature of their rooms. Mr. Charles Yonson, of Maryland, who found his eggs hatching when he received them, and kept them in an ice house until the 22nd May, when they were found to be very damp and mouldy, exposed the eggs on that day. On the 29th of May they began hatching. About 20 hatched on the first two days and died. The fifth day's batch was the largest and most vigorous. Mrs. M. Alden, of Rochester, also kept eggs on ice from January to the 25th May, when she exposed them; 1850 hatched from 2,000 eggs on 8th to 13th June; 1,000 of them on the 12th June. The fourth day's batch appeared to be the most healthy and hardy of all. Miss Esther M. A. Marett, of Philadelphia, tried to feed the newly-hatched worms on parsley and dandelion leaves, as well as on lettuce (mulberry and osage orange leaves having been killed by frost). They would not feed on parsley; fed very sparingly on dandelion, but fed well on lettuce for twelve days, and then most of them died. From 350 worms surviving and fed on mulberry, 296 cocoons were obtained, all but one of which proved sound. Mrs. Witherspoon, of Texas, states that she fed the young worms on lettuce and elm buds, on which they lived for several days and made healthy worms. Miss Mary Mills, of Alexandria, fed the worms on black mulberry leaves six times a day, hatching them on 7th and 8th June. She was unable to control the temperature of the cocoonery, which ran from 75 degrees to 90 degrees Fahr. Her French annuals, which were very large and fine worms, died by the thousand just as they were going to spin. Some few worms which hatched in the first week of May, and which were kept in a garret and fed on osage orange, made the largest and finest cocoons she ever saw, and very few died.

Mr. William P. Haywood, New Jersey, hatched out about 95 per cent of the eggs sent him, and about that percentage made very fine cocoons. He raised two crops of cocoons; the second crop smaller, but finer in texture, than the first. The worms were fed on cut branches of morus nigra, seldom fed on Sunday, and when the weather was rainy only fed every other day, but liberally. Worms placed in a mulberry tree outgrew those fed by hand at least 50 per cent, but the birds got them. Mr. Haywood reported his intention of putting up a reel this winter, but says it will not pay to raise silk unless the duties on raw silk (2 dollars per lb.) are restored. It cost 2 dollars per lb. to reel silk, and as reeled silk from China and Japan now costs from 4 dollars to 6 dollars, only 2 dollars to 4 dollars are left for the purchase of cocoons and for profit. Mrs. Martha B. Bond, Ohio, fed her worms on "nativo mulberry." The temperature of the cocoonery was about 60 degrees Fahr., and the weather wet the most of the time. She had to have a fire in the room all but a few days. She does not think six died of sickness out of the whole lot, after she got mulberry leaves for them, although many died while being fed with lettuce at the outset. A thousand lived to spin cocoons. Mr. Charles Yonson fed his worms on osage orange from a hedge until about the last age, and then fed osage orange from trees. He mixed a few morus multicaulis leaves with those of the osage orange. He obtained 971 cocoons, 33 of which were soft. The remainder were 574 yellow (Japanese), weighing 29 oz., or 317 to the pound, and 364 white (Japanese), weighing 14 oz., or 416 to the pound. The temperature of the cocoonery was 70 to 80 degrees Fahr., excepting a few days in the last age, when at times it was 65 degrees.

Mr. Joseph J. Smith, of West Philadelphia, fed the worms entirely on mulberry leaves, principally the white variety, eight times a day. The eggs were not exposed for hatching until 29th of May, having previously been kept in a cool cellar. They hatched very slowly, and half of them failed to hatch at all. Fifteen per cent of those that hatched were unable to spin; the rest did very well, but made rather small cocoons. The worms were kept in quantities of about 200, on sheets of newspaper, and transferred to fresh sheets every second day on fresh leaves. The weather was generally fine and warm; only a few cold, wet days occurring. J. Herbelin, New Orleans, reports having obtained in 31 days from date of hatching cocoons of first

quality, 160 to the pound; 107 lb. from 1 oz. of eggs; worms fed abundantly on white mulberry only. On 2nd May, 1883, he reported that he had raised 2,500 lb. of choice cocoons in his three cocooneries, and had imported persons and looms from France for reeling, and was having 15 reeling looms made according to his own invention. Later he sent specimens of his reeled silk, the first specimen being somewhat coarse and brittle, but the last making handsome skeins, and showing rapid and marked progress in the reeling. James Hyatt, Dutchess County, New York, reports that of two packages of silkworm eggs sent from your bureau to me, one netted 12 dollars to a lady to whom I gave them, and the other furnished 1,200 or 1,300 cocoons not yet marketed."

A portion of the report is devoted to giving publicity to such notices as the following:—"Mr. Samuel G. Stoney, of Charleston, S. C., offers to furnish cuttings of the osage orange, morus multicaulis and morus alba, at 1 dollar 50 cents per 100, in any quantity, cuttings to be from 9 to 12 inches long;" and allusion is made to the Mississippi Valley Silk Culture Enterprise Company, of Missouri, having issued on the 19th January the first number of a *Silk Culture Directory*, to be issued weekly for the silk raising term. In this they offer to furnish to praties within reach of their headquarters silk caterpillars already half grown, to be reared by these parties on half shares, thus assuming the risk of the proper hatching of the eggs and of the success of the subsequent culture. The *Silk Culture Directory* contained instructions in the methods of rearing silk caterpillars, with illustrations and correspondence. Mr. Virion des Lauriers, New York, stated that he had market for more cocoons than he could supply. He distributed early in the season the prospectus of a mulberry nursery and model school farm and cocoonery, to be established at the South Jersey Silk Colony, Bridgeport, Burlington County, New Jersey, on the plan of the school farms and cocooneries of France; but later he reported himself from the Virginia Silk, Farm, in Genito, Va., where on the 10th June he was raising the issue of 27 oz. of eggs, expecting to get from them 500 lb. of dry cocoons, besides those set aside for the perpetuation of the breed. Mr. des Lauriers reports himself as sole agent in the United States for the French Government silk school farms and nurseries, and as an importer and dealer in silkworm eggs, mulberry trees and seeds, and silk culture requisites; and the report concludes with a notice sent by the organisation in New Orleans of an association styled the Southern Silk Industrial Association, for the sale of silkworm eggs and mulberry trees. Cocoons obtained by the association from worms fed on white and black mulberry combined are reported of good quality, moderately large and firm, and the moths free from disease.—*Leader.*

AGRICULTURE ON THE CONTINENT OF EUROPE.

(*Special Letter.*)

PARIS, September 6th.

FARMING—MILK AND COWS—ENSILAGE—BREWING—SUGAR.

French farming is passing through an evolution, the result of the terrible law of the struggle for life. Since ten years the owners of small patches of ground, won by a life-time sweat of the brow, are selling their little properties and becoming comfortable farm laborers, so that the miserable patches of land will be consolidated, worked with capital, and directed by modern, scientific skill. So much for the soil.

The processes of farming are also being revolutionized. Leaving the culture of the vine and beet aside, the soil tends now to be appropriated to cereals, milk industries, fruit and kitchen garden products. The first and third have been ever in favor, but are now being more intensely pursued where natural circumstances either favor or compel. Milk industry, to which is joined the production of meat by precocious races of stock, is akin to an innovation. Indeed it has been forced on French agriculturists by the severe competition in butter and cheese on the part of Northern Europe and the United States. It is every day becoming more difficult to get off stocks of butter from Normandy and Brittany, and old prices are still harder to obtain.

Respecting milk farming: to be successful two conditions are essential, a proper race of cattle and suitable and sufficient food. France possesses some excellent local breeds of cattle, which, if the milch cows were selected for their speciality, and crossed with a herd-book Durham bull, the result would soon repay the attention. In this amelioration of races the weak point with French breeders is, that they rear the bulls resulting from these crossings, instead of having them cut and converted into excellent oxen. And French agricultural societies are much to blame for admitting such mongrel bulls into competition. The tendency now is to cross selected local races with Durham blood; the Flemish cow unites the most of the desired advantages.

Though the food may be liberal and good, if the cows be lean, they cannot yield milk rich either in butter or cheese. The renovation of the tissues of the animal economy presents the secretion of milk. The food has also an important determining influence, and the kind of water supplied affects the flavor of the milk; it is to the latter circumstance that is attributed the objectionable quality of Dutch cheese.

Milk is a little heavier than water, and when pure, of an opaque whiteness, possesses a milk flavor and a slight odour. Some question if it has a yellowish tinge. The milk of pure Jersey cows is decidedly yellow in color, and like the Breton breed is rich in butter. The Channel Islands cows are estimated to yield one pound of butter per day per animal. The density of milk varies then with the race, food, age and health of the animals.

Schiehler says the milk of cows submitted to a good *régime* and house-fed contains in 1,000 parts 24 of butter, 110 of cheese, 50 of skim milk, 77 of sugar of milk, albumen, lactic acid and mineral salts, and 739 parts of water. Light-colored cows are popularly believed to be better milkers than dark maroon or reddish brown, but their milk is not so rich. Climate affects the yield of milk as transpiration is greater; thus the cows in the south of France are bad milkers, while the contrary is the case in the north. Cold is equally objectionable, the mountainous districts prove this, where the temperature, not the pasturage, is at fault. Neither young nor old cows give much or rich milk; they are in their prime after the third calving, or when four or five years old; then the organs of secretion are developed. An animal cannot develop itself and yield a satisfactory supply of milk at same time. Cows may remain profitable milkers till twelve years old. When aged from six to eight, and about six weeks after calving, a cow if "spayed," will, it is alleged, secrete one-third more milk and uniformly for a longer time.

Cows fed on green or aqueous food will yield most milk. White clover tells handsomely on the quality of the butter. Then ranks natural meadow, superior to artificial, because containing a greater variety of grasses, and of an aromatic and condimentary character. Marshy forage is in every way detestable, chicory is bitter, madder colors the milk, while spergel trees tell on the quality. De Weckherlin considers potatoes increase the quantity of milk at the expense of its quality; mangolds are satisfactory, and carrots more so. There are dairy farmers who can command what price they please for their butter; well, carrots and prime hay, and white clover soiling given, not much at a feed, but frequently, is the stage secret of their success. Grains and wash were formerly in more favour, but are considered to fatigue the digestive organs; cabbage and dry fodder are esteemed; artichoke leaves impart a bitter flavor, while pea-pods communicate a peculiar taste to, while reducing the quantity of milk. In the cheese factories the latter stuff is blamed for preventing the milk from curding. Oak and ash leaves mixed with forage are said to produce butter of a waxy, close-grained nature, possessing a nutty flavour.

In France and Italy the milk of a cow after calving is not considered to be in its normal state till ten days; at this stage it is called *colostrum;* it contains no caseine, turns rapidly, but does not acidify. It has been alleged the longer the milk remains in the adder the richer it will be, hence the morning is superior to the evening milkings. Wolff's experience does not confirm this. Milk may not only be bitter as a consequence of marshy fodder, but also from the animal's bile, entering into the circulation and so passing to the milk.

Associated dairy-farming in France has to struggle with the legal difficulties which fetter the formation of co-

operative societies. The system is destined to render important services to small farmers, distant from centres of population, by economising expenses. Pigs fattened on the small milk, when it is not made into cheese, will suit many farmers; pork so fed, with bran or meal added, ever meets with a remunerative sale.

Nothing succeeds like success. Ensilage has hardly been founded as an essential to modern farming, than attention was naturally devoted to the possibility of dispensing with costly trenches in masonry and machines for chaffing the green stuff. M. Cormouls-Houles and his brother have perfectly preserved green soiling in the open-air; they reside at Mazamet (Tarn), and invite the St. Thomases to come and see. One brother who had expended a little fortune in constructing trenches, with cement linings, has now given them up for the simple open-air plan. This consists in stacking exclusively green fodder, on a bedding of rough stones, and on a dry site, covering the mass with a weight of 20 to 30 cwt. per cubic yard. The whole secret lies in this pressure. In the silos the crust of the mass, to the depth of two inches, is unfit for food; in the open-air stacking this thickness is doubled.

In the brewing of barley only a very small percentage of the proteine or nitrogenous matter enters in dissolution. Of the 15 parts of nitrogen contained in 1,000 of barley, nearly 10 parts remain in the "grains." After microscopic examination by Wolff and Kuhn, this is due to the gluten-cellules remaining intact. The great objection against grains was the great volume of water they contained. To remove this inconvenience an establishment has been erected at Munich, for drying the grains by steam. This prevents their acidification and decomposition. In their natural state the grains contained 78 per cent of water, when artificially dried but 20. The factory is only in work since January last. The proprietors guarantee that the dried stuff contains 26 per cent of proteine and 42 of non-azotized matters, and the purchaser can have it analysed at the government laboratory at the seller's expense. It is contemplated to similarly dry beet-pulp.

The harvest operations are terminated under splendid weather. The yield of wheat will be very good, superior to 1883, but under that of 1882; the other cereals will be on an average. The vintage and beet, the former especially, will be satisfactory; the recent rain has benefited both. As France has sufficient bread stuffs this year, and the protection policy being in vigor by the government, a tax on foreign corn is contemplated.

France is behind Germany in sugar industry; the latter has made the fortune of the Tuetonic agriculturists, who can always count upon 17 to 18 fr. per ton for their sugar beet. But then the cultivation of the latter is not a half-and-half affair; the aim is sugar. The growers also, to be extent of 80 per cent of their number, are owners of the sugar mills on the principle of co-operation. The soil is such though light, and does not suffer either from excessive drought or humidity. Two horses suffice to work, where in other countries four would be necessary. Then manual labour is cheap and not sparingly employed. Lignite, or soft coal, can almost be obtained from the surface of the soil. The difference between the sugar industry of Germany and France will be better comprehended from the fact, that while in the latter country it costs from 25 to 30 fr. to produce a beet rich by 12 to 14 per cent of sugar, in Germany the combination is one-third less. In Germany also the roots are stored in pits containing 4 to 5 tons in the fields, and delivered at the factories *pro rata* to their wants. No farmyard manure is employed, only chemical fertilizers, and the azote is in the dose of one part for every two of phosphoric acid; the nitric rather than the ammoniacal form being preferred. From 10 to 13 lb. of seed are allowed per acre, the rows are 16 inches asunder, so as to yield about 72,000 plants per acre; 18 to 20 tons is the return per acre. Manure for cereals and potatoes is applied in the compost form; along the highways heaps of such are to be encountered in course of preparation. Not much wheat is cultivated; the same may be observed of oats, rye and barley, the latter, the chevallier variety, are most in favor; the grains are sown in lines and well weeded. But little land is under forage, rarely lucerne, clover, or sainfoin are to be met with; instead, beans and peas are cultivated. There are also immense breadths of land under potato for cattle feeding and distillation. The borders of the highways are planted with cherry, apple, and pear trees, and the sale of the fruits brings in a handsome revenue to the authorities, while securing work to the people. Dutch and Swiss cattle are preferred for house-feeding, and the centrifugal creamer is in general use for butter farming. The Germans do not rear many barn door fowl; the goose is the bird preferred. The food for stock is chopped, crushed or cooked, and all scientific improvements eagerly adopted.

Dr. Valin has made his official report on the prevalence of phthisis, in cow stables, in cities. The disease is unpleasantly general, and contagious by the milk.

COFFEE LEAF-DISEASE IN INDIA, CEYLON AND JAVA.

Ceylon Planters' Association, Kandy, 11th October 1884.

(To the Editor of the "Tropical Agriculturist.")

SIR,—I am directed by the Committee of the Planters' Association to transmit to you the enclosed paper on "Leaf-Disease, its Cause and Antidote," by Mr. Edgar A. Quarme, India, for publication should you deem fit.—I am, sir, yours faithfully, A. PHILIP, *Secretary*.

LEAF-DISEASE, ITS CAUSE AND ANTIDOTE; NON-PRODUCTIVENESS, ITS CAUSE AND ANTIDOTE.

Leaf-disease attacks trees in a sickly or delicate state of health. So with larger fungi which settle on trees in a moribund condition, the fungus gathering strength according to the tree's debility. Potato disease falls upon the plant during its greatest efforts, when enlarging its tubers, flowering, and seeding: the exhaustion is to be noticed by the roughness of the leaf.

2nd.—It is in these stages of effort through the year that the coffee tree is the victim of disease, and they are *increased in* number and duration by the present system of cultivation in India and Ceylon, the system having the effect of *putting the tree out of its natural season*, and preventing *hibernation*. It might be argued on the other hand, that nursery plants which are exempt from this treatment have leaf-disease. This is answered by stating, that their delicate structure, in conjunction with the great effort the plants are making in growing, added to a *congested* state caused by the difference of temperature, the result of excessive watering or rain, cause this condition.

3rd.—Among other causes and their combinations is, early pruning. The after effect of pruning, flushes of wood forced out on the tree in its efforts to replace that taken off at the wrong time, three exhaustive handlings follow, and if a favourable blossoming season, *overbearing*. The use of unfermented manures on low elevations and clay lands. Renovation pits in *like conditions*, causing congestion to the tree, here to be called "wet feet." Manure put in wet, in any weather, generating fungus. Neglect of cultivation, causing debility to the tree, want of means or labour come under this head. Sudden bursts of sun after rain augment this also causing congestion. Denuding roots by mamoty, and other weeding, the most valuable roots are exposed to the sun and weather, collar roots to be hereafter designated as *fruit sap roots*. Doing things at the *wrong season*. Here too much cannot be said against continued monthly weeding without burying at once, also removing weeds from the land is taking off a crop each time it is done, and leaving the surface to be washed off by rain or to be injured by the sun which destroys vegetable and animal substances, which is one cause of shade being so beneficial to coffee, constant handling without burying, there is each time so much cropped off the land.* A very serious attaint in the note below against the system carried on in India and Ceylon which of itself would appear sufficient to answer the able and interesting letters of "W." which, whilst writing a copy of this paper, I noticed in the *Tropical Agriculturist* (a

* It cannot be gainsaid, as a writer to the *Tropical Agriculturist* of Ceylon says, where there are 12 weedings, 1 pruning, 2 handlings not buried in, left on surface, *nearly-all* but silicates *are lost with* crop, 16 crops! in a year, beside sun injury and wash! "What ails our coffee?"

most valuable journal) a letter by another writer as per note. It is, however, necessary to make this statement to bring the matter home to all of us. Early pruning as has been before said first *wakes* the tree up from its natural period of rest after crop. *So as soon as a coffee tree begins to bear it has no chance of hibernoting*, which if not allowed in tropical climates, the tree stays of itself from bearing "fallows" if so inappiopreate a word will give my meaning: persisting in it is *non-productiveness*.

*Non-productiveness and Leaf-Di·ease: their Antidote by Till-age.**—Take an estate fairly situated on average good land, good planting, on either a high or low elevation. The crop will be picked, *and it is to be hoped the ground carefully gleaned* on part of the estate by the middle of January. Give a cooly a "koikut,"† a sharp pruning knife, and two sticks, one 8 feet long and sharpened at the end, the other, three feet long and forked at one end and pointed at the other. On the lower side the coffee tree, place the 8 foot stick underneath the branches, resting one end on the ground, lift the other, at the same time pressing the point obliquely into the ground. Support the lifted end by the forked stick, placing it, so that it shall resist the greatest thrust of the branches, so leaving a space for the man to work under. With the koikut he will scrape off all the surface soil, and pick the earth away, till the the main roots appear, between these he will pick the earth till other roots are exposed, excavating a space 3 feet square and about 9 inches deep. The first sap roots, if any, he lightly clip the ends. I mean the collar roots growing out of the stock-column of the tree and are found by experience to be the best for manuring, *if they may not be really designated as literally the* SPECIAL "FRUIT SAP ROOTS," as it is singular to notice their absence in trees that have stopped bearing. My experience and careful observation over many years, in singularly fortunate occasions, where roads and waterways have been cut through fields of coffee (I have often gone several miles to notice it on other estates as well as my own) I believe them to have this special function. Myself, the late Capt. Godfrey, and also Col. Scott (who is a most successful planter wherever he opens up). We all put the manure mixed with earth about the collar roots, since it also got at the *ends of the roots* to the spongioles, leading naturally *first up the tree* and *so first* as in Europe setting blossom; *afterward* the thin abundant leaf sap came up and set leaf. The late Capt Godfrey manured in the dry spring, when others were busy pruning, on about 100 acres, he had alternate years from 60 to 80 tons. On one spot of 17 acres he showed me, *he gathered 40 tons in one season*. His nephew, the owner of Ambly Mulla, Mr. Sinclair, can also prove it: it is difficult to credit—I do. As Dr. Trimen informed me, it would take great care in observation, even many cases to prove it. My experience since 1860 has proved it to me, and without doubt it is the most suitable place, putting manure to the sides of roots is like putting oil to the side of wick with the fibre end sealed up. Let the doubting try this. We know that there will be a difference, nature adapts itself to man's want of knowledge, *and make roots* at sides: this is why their spring manuring is slow in effect.

I should be glad to see the able writers take up this question in Ceylon, so I look for valuable experiences and opinions based on them, for or against what I state. I shall designate them *fruit sap roots*. These as I said (if any) will have their ends clipped. Should there be none, a shaped incision on the column will induce their growing if done *only skin deep*. Parasite roots will come away with the hand.* Alternate secondary roots will be cut off from the large primary roots alternately.

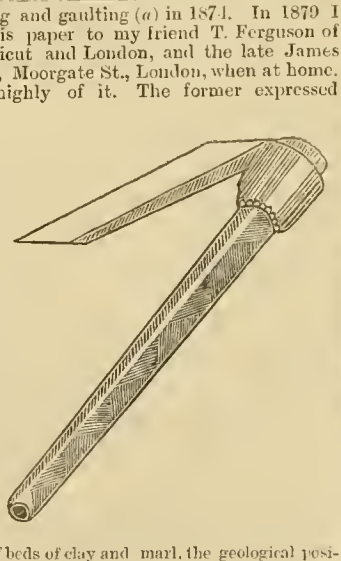
If the weather is windy, hot dry with sun, leave the roots exposed *till the old leaves fall off or are ready to drop and the new leaf and wood is limp*, AND ALL BUT WITHERING. The wintering must be so complete that an *absolute cessation of action must exist* as is produced by winter in high latitudes. There will be local, and atmospheric circumstances that will cause longer wintering, altitude, shade, cloudy weather, rain &c. The planter need feel no alarm. Those that die (if any) he will be well rid of,† since they never would give a paying crop, somthing being wrong with their tap-roots. *The shortest time will be ten days' exposure*. After the full signs of withering show themselves, apply manure *as dry as the soil* on the land. It is done quickly by placing it on the field in convenient parts sufficient for its area. I apply 30 lb. to a tree—more on this will follow, but it will be sufficient here to say, that the manure will be mixed with its bulb of earth, and *placed about the collar "fruit roots,"* and the earth covered in, care being taken to place all roots as much in their former place as possible. Shola earth or bone meal. If nothing cover in as above. It will *be found that this wintering is so beneficial* that until a crop has been borne, *there will be no perceptible difference between that manured and that not.*‡

Only well-planted trees will take kindly to wintering, since their tap root and ends of primary roots will be all that keep checked life in them. *It has been noticed here and in Ceylon, after a dry season good crops have followed, the plants got partial rest. Why and how* this cessation of action *develops or affects fruit* sap I do not presume to know. At present I can only think that early pruning *disarranges sap* by inducing the flow of wood sap to replace wood cut off by early pruning, so *reversing* the order of nature, since the *fruit sap should first rise*. The tree is not only *disturbed*, but the *large flow of wood sap deflects and carries up the lesser in bulk fruit sap*, thereby mixing with it on its way up. As before said, in high latitudes the *fruit sap comes up first and sets the blossom* on the apple, cherry, plum, &c., come first, AFTERWARD THE LEAF.

* I began wintering and gaulting (*a*) in 1871. In 1879 I showed a copy of this paper to my friend T. Ferguson of Hinde & Co., of Calicut and London, and the late James Gordon of Boyd & Co., Moorgate St., London, when at home. The latter thought highly of it. The former expressed no opinion.

† This tool is used by the natives of the Salem District, Madras Presidency, for weeding their fields. The hoe is set at such an angle to the "eye" to receive handle, as keeps the hoe directly in the curve of the stroke, consequently giving each blow its greatest force: of country iron a blacksmith makes 6 per day.

Length of blade 7 inches, breadth 1½ inch; about 1½ lb. or less in weight.



(a) GAULT.—A series of beds of clay and marl, the geological position of which is between the upper and lower green sand. [*Prov. Eng.*]—LYELL.

* In 1873 I found so many parasite roots in trees covered with leaf-disease in October, that I thought the disease was caused by the exhausting effect of them (?); the trees had heavy crop and were manured 30 lb. to a tree in the spring, pruned in January and February.

† One year in the Shevaroys there was no rain but a few cents from end of October to middle of May in the former year.

‡ Though the above system is new to coffee in Munzerabad, Coorg, Wynaad, Nilgiris, Travancore, Ceylon and Brazil, &c., &c., I do not presume to put it forward as original or any other part of my system, say gaulting, which has been in use in Europe for over 100 years, and wintering has been applied to fruit trees brought from temperate climates to half-tropical or those of half-tropical to tropical climates *to enforce bearing* when otherwise they would not. This will I trust recommend it the more to those owning coffee or having extensive and important trusts for others and I trust specially to the few remaining pioneers, the fathers of the enterprise in Ceylon. To such old planters living and departed respect and veneration is due. No one feels it more than I do, who though entirely differing from the system they introduced. It was the first evolved, bringing order out of chaos.

If this is so, what disorder early pruning causes? Beside intruding and actually *stopping all hibernation henceforward so long as early pruning is followed out in coffee.*

Wintering may be carried on to the end of March, sometimes to the middle of April, blossom or no blossom. If lost by this process, there is always *four times* as much blossom as is required for the tree to develop into fruit. The *rest* is turned into *sleep* by nature, and this method *continues* the *hibernation developing at one time all but cessation of action, giving* $2\frac{1}{2}$ *months' repose where there was none.*

Shrubs leaf later than large trees. In April the storage of developed force will burst out, and it will *be found that there is no great vitality that the dew is sufficient to set blossom.* However, the wintering having the *reverse* effect of pruning, puts the blossom as far back as nature will allow, a month later than if *not* pruned and *not* wintered, *and* $2\frac{1}{2}$ *months later than at present, where the pruning brings out blossom* $1\frac{1}{2}$ *month before it otherwise comes*, beside which, the tree gets into A HABIT *of blossoming early.* The blossom will be so abundant on these wintered trees, that it will be found to come out in old primaries and the stock of the tree, as I have seen it on coffee over 30 years old, and at a time when rain in India can *safely* be counted on *after 15th April.* After June, it is simple root pruning, which is very good.

There is a superstition among planters of even great experience, that blossom coming out in rain does not set. There are no such rains likely to occur as could destroy blossom, and my experience goes to prove, with that of another planter who has carefully *noted* and *recorded* it, that in healthy trees there is no harm done. It may be so in sickly trees, and in Ceylon where the rainfall appears so different to that* of Wynaad and the Nilgiris. Here it is not to be feared. I have seen our best blossom set in May on the Shevaroy Hills. While the tree is bursting out to life will be found the best period to again strengthen it, as it *is a period when great vital strength is necessary*, and the additional strength afforded will endure blossom to set. Indeed the planter must do all he can to aid the tree, *strengthen it and relieve it by* PRUNING. On the wintering ending by a burst of vitality the planter must harden his heart and *enforce his coolies often to cut away one-half* or a third of his blossom. *It is only after seeing what blossom he has* that he can *with certainty* prune to the exact amount of crop he requires the tree to be kept to, as formerly it was as *equally uncertain* what crop *the season* would produce; if a *good* one, he had the curse of a bumper crop, injuring the trees for three years, on poor land killing them, or abundant flushes one after the other forced out six weeks before their time, with *all but absolute certainty* that *there will be no rain* but chance dews to set it in. Dew is only able to set highly-manured trees, or those in great form.

I have had it told me that pruning could not be done in April, May, and June. My reply is, *it is better not to prune at all with present deplorable results of present system.* But since Mr. Bilby, Hillgrove, Coonoor, has taught women to prune, beside which here there is plenty of intelligent labour to be got in Wynaad when the Canarese are away in Tamils which they turn up their noses at, also Churmas and Moplahs.

To the experienced planter it would be presumptuous to tell him how to prune, since he can do it to the cwt. To the less experienced I would venture to advise, 1st, *be sure that whatever blossom is here left on will all bear.* 2nd, the tree must only have enough on it to bear without *effort* the two following years the *same crop.* There will come out an amazing storage of sap ready to make more blossom in old primaries and stock of tree likely in June. Trees bearing 15 cwt. prune back to 10 cwt. or less. Cut away a third of the blossom on heavy bearing trees—trees that have had no manure for two years—and those on poor land, a fourth as a rule will be cut off. I advocate light pruning. *Prune to limit bearing and keep the tree in shape. Entirely blot out the old rule, i.e.*, wood that has born once is not to remain on, *it* WILL *bear again*, only giving the preference to the healthiest wood and *simplicity* of method which a cooly *can* follow. Some I have seen that the operator could not explain. Where there has been leaf-disease *prune freely.* Wintering has the effect of developing fruit but *minishing* wood. So pruning will encourage it. Heavy pruned and early pruned trees become "*dropsical*" in appearance both stock and primaries with little fresh wood. Column root and primary roots, the former devoid of fruit roots all thick and heavy, and the latter with a few old wiry fibre roots having no spongioles. The hacked victim stunned by heavy early pruning but dropsical from checked sap *cut down with a saw obliquely* 6 inches from the ground. Then cut down with two cuts intersecting at centre in form of a crop to a depth till the cut is 1 inch from the ground or roots. The tree will send down new tap roots, and send up suckers from under the ground often. Leave four till the sap is fairly relieved, and one dominates. Only *as a last measure* dig the tree out. Supplies are said to be a failure. They do badly in old coffee, but the following is a good plan:—A large ball plant put into the pit two persons planting, one holding the ball. After it is planted put a ring of chisel-sharpened stakes in the form of a ring, driven in touching each other $1\frac{1}{2}$ foot, at a distance of $2\frac{1}{2}$ feet from plant. This will *sever the neighbouring plant roots*, their rotting will not signify since an outer ring can be put at any time 6 inches from the old one.

Handling.—Do this with the *knife* and *not* with the hand; the remaining shoots are lacerated, and crop lost by pulling off.

Manuring.—25 to 30 lb. of dry cattle and 12 lb. dry goat manure per tree. *Do not try and put less to get more done, you deceive yourself and your proprietor.* Manure once in four years, supplementing it in the third year by bone meal as much as a woman can hold in her two hands to two trees. I knew an estate paying well where one piece twenty-one years old, which has never had manure of any kind, only tilled. Second year winter all trees, those manured last year only make a ring pit, leaving manure intact.

Caulting.—All that cannot be manured and is too steep to dig 15 inches deep, dig trenches in alternate rows oblique if necessary to secure *easy gradient along side of hills,*

* From a copy taken from a rain register carefully kept by Mr. A. C. Griffin from 1863 to 1884, and now kept by his manager, Mr. Diekins. It will be clearly proved that neither January, February, and March to middle of April is there a semblance of a good rainfall. Average of rain for 22 years:—January ·03 in.—For 15 years there is no rain in January! February ·29 in.—For 15 years bar a fall of ·07 and ·05, there is none in February! March 1·50 in.—For 3 years no rain in March, 6 *years under an inch!* April 3·11 in! —Nearly all the rain falls after 20th April. May 7·00 in.—For 7 years the average rain in April is *under* 2·00 in! Bar an unusual cyclone in January when 3 in. rain fell, the average for 22 years is 0·18 in. For the information of those it may interest I copy the table. It shows that the rainfall now does not differ generally from that of the past 22 years. Rain in January and February is like rain at Aden, unaccountable when it does fall:—

trench 1½ to 2 feet deep and 1 foot wide. A cooly will do 12 trees. Into it if there is stone, fill it; over this put grass or weed; failing stone fill with brushwood. End of gault trench is to open on *drains*, *roads*, or *streams*. This plan *absolutely stops wash and prevents* "*wet feet*," and lasts for an indefinite time.* The rain water percolates into the land, leaves all the land requires, and passes off through their subsoil drains. It costs only R10 per acre!

Digging.—Do this the same as a nursery on level land, starting with a trench made two feet wide—do it with *pickaxe*—and remove the earth behind with mamoty. It is the only method of getting rid of "Moram grass," or as it is called in Canarese "dobbahoolo." Fern is treated with ignorant indifference by those who ought to know better. It is a most harmful weed. On the Shevaroys R50 has been paid to get it dug out of one acre.† Digging is estimated at from R15 to R20 per acre in Wynaad. Third year winter as second year; manure as before. Dig as much as possible and gault steep laud.

Note.—While revising this paper, I notice a reference to General Morgan's Prize Essay, which I regret I have not read in the *South of India Observer' Planters' Supplement*. The writer, after touching on the loss of potash by coffee crops, referring to the essay, "the writer shows that nearly all coffee soils have a subsoil composed of decomposed felspar, which, on an average percentage of 18 per cent of potash, here is the panacea for his loss ready to the planter's hand, who has only to dig up and lay on his land the amount of felspar which will supply his loss of potash 600 lb. For instance, to meet his loss of potash, he will require about 4,000 lb. of felspar to be on the right side. The writer of the treatise explains that being spread on the surface of the ground, the potash by the action of the weather and carbonic acid in the air become liberated and fit for plant food. That so long as it remained in the ground, bound up in silicates, the roots of plants are quite unequal to the task of assimilating the potash."

Wintering, Manuring, Gaulting, Digging, and *Renovation* pits in *porous upper and subsoils* (this is all that has been on the 25 acres I referred to, which is 20 years old and unmanured, tilled by renovation pits) this is TILLAGE. *When persons are not able to do this, let them lose no more time but cut coffee, for they cumber the land by owning it*, and the man who cannot command labour must be sent away for one who can.

Wintering is singularly beneficial for trees under shade. Fourth year manure only undug and ungaulted land It ought to be protected from rain, both for reasons named and convenience of carriage. A paper in the *Gardeners' Chronicle* lately went to prove that exposure to sun did not harm cattle-manure. This would seem to be confirmed by the good results of the scant manuring in the lowcountry. Certainly rain on stacked manure is bad.

Manure put in at the time of the year April, May and June, 30 lb. to a tree does stop leaf-disease. In August onward I have found it cause leaf-disease to follow. And likely this was the case with trees brought to an expert's notice. He writes me on leaf-disease:—"There is only *one* cause of leaf-disease—the spore of the minute parasite *Hemileia vastatrix*. Given these and moisture in which to generate on coffee leaf, and everything else follows. So far from attacking by preference sickly trees. *Ceteris paribus* (a saving clause for your doctor) *Hemileia* flourishes best, when it lives in and feeds on the finest and most juicy leaves, and no system of cultivation that improves and invigorates the coffee can help benefiting the fungus also to some extent, and but of course good cultivation and nutrition *help the trees to bear it*. *Hemileia* may disappear. I do not expect this, however. If it do so, it will be due to some general causes of a climatic character of some years' continuance." When the vine disease and potato rot have continued so long, it does not look on the face of it encourrging to coffee—only a radical and a practicable change of treatment will do good, and I believe this to be the best. At the same time I have the great disadvantage of not having been in Ceylon, so I dare not speak with the same assurance of my system being a success there. Though I infer it will be of great benefit when I consider that the present system is not in harmony with what is known of the culture of trees in tropical climates.

1st.—Col. Money, in his excellent book on tea, insists that tea should have a time set apart to hibernate a plant that is only cultivated for its leaf. This leaf, we know, takes less out of soil for its structure, and very much more out of the atmosphere and water than a "nut fruit" like coffee. So how much the more coffee that has more severe calls on soil requires hibernation. 2nd.—Wintering has been found to enforce productiveness in trees that in tropical climates would only blossom, as noted by Sir E. Tennent of the cherry tree in the Ceylon gardens. I look also to this paper having the effect of waking up in old planters old experiences and observations which only require waking up, since I have had many good hints on coffee given by men who have knocked about, namely, barristers, doctors, military men, sailors of kinds, farmers, padres (particularly Roman priests), shopkeepers, engineers, &c., who never saw a coffee tree before. Truth like gold must be sought after, and here it can be only done by shaking and hearing what other men's experiences are.

Before I close I must refer to Ensilage. I never heard of it before last year, though it was known 50 years ago as a farmer friend tells me. It ought to be most useful to those estates with little grazing. Since, I learn that five head of cattle can be kept on the same area one was formerly.

I cannot set my system before planters as a panacea for leaf-disease or non-productiveness, but it is in harmony with all known European and tropical agriculture, and I have proved it.

Manure put in at the right time is here Glenvans, a preventive of leaf-disease, 50 lb. to a tree. It may not be so in other parts. Also since it is quite impossible to cattle manure one-twentieth of the estates, I should be doing little to help my fellow-planters by giving a specific which very few could have the means of using. So it will be found that my system specially meets the difficulty. I meet the want of manure by *tillage*.

Wiutering without manure can give	...	...	2 crops
Gaulting do do	...	...	2 do
Digging really 15 inches deep gives	...	...	2 do

On Glenvans renovation pits alone have made 25 acres give paying crops, and my extract for General Morgan's letter gives the reason. Here an estate can go on 6 years without even bone or any patent manures.

I have no hesitation in stating that if this system is carried out, it will more than fulfil what I have stated, and I look to King Coffee becoming remunerative as it was in better times.

I conclude by laying this paper before the Planters' Association of Ceylon, leaving it to their unbiassed judgment to approve and *test by* results, and leave it entirely to you to give me such remuneration as the value your ample experience will be able to discern, and I look to free gifts from those owners who benefit from applying my system.

In reading this paper I trust due allowance will be made for the great difference of seasons in Ceylon. Local experience of localities can only fix the time and season.

EDGAR A. QUARME.

4th September 1884.

Note.—I see by the Ceylon papers leaf-disease is less: this is, I believe, owing to the very dry season having increased the period of hibernation.—E. A. Q.

* This mode of culture was carried out over 30 years ago in the Ootacamund Botanical Gardens. It is effective up to the present time.

† Dug up soil last usefully open over 20 years.

KERR'S TEA ROLLER.—A planter gives the following opinion on this roller:—

"Since writing you last I have been travelling a good deal in the tea districts, and seen a good deal of machinery at work, I can still honestly say that your roller turns out as good work as any. I expressed myself so, but people have got an idea into their heads that the machine is not so good as others: a great deal of harm has been done by inferior workmanship. Of course, I explained that the fault of the first put-out machines lay in the build and not in the principle of the machine, but I could only explain this to people I came in contact with on the subject. Two days after the first report appeared in the *Observer*, I had a request to show your machine to two friends,"

THE *TROPICAL AGRICULTURIST.*

We may be pardoned for making some special allusion to this publication, because it has now assumed so thoroughly representative a character in connection with this colony and its agricultural industries that we consider its status, gradual improvement and extended circulation are matters of interest to all who desire to make the position of Ceylon and its new products generally known throughout the world. Since politics or news in the ordinary acceptation of the term find no place in its columns, our monthly periodical is open to be judged on practical issues alone, and that its value is appreciated is shown by the increasing favour bestowed on it, not so much in the land of its birth as in other and widely distant countries all round the globe. Perhaps the highest testimony to its value comes from such men as Sir Joseph Hooker and Mr. Thiselton Dyer of Kew, Dr. King of Calcutta, Dr. Bidie of Madras, Mr. Morris of Jamaica, Baron von Mueller of Melbourne, and the Directors of the Government Botanic Gardens in nearly every colony of the British Empire. They all feel that the *Tropical Agriculturist* supplies a felt want, and the Government of India has recently indicated its approval by ordering copies to be kept on file in all the Libraries of the Public Museums as well as of the Horticultural Gardens and by the Directors of Agriculture in the different presidencies and provinces. In Ceylon, it is something to find the Committee of the Planters' Association recommending papers for publication in this periodical, an example which we have no doubt will gradually be followed by the District institutions and by the Agents of Government who take an interest in promoting agricultural development. We shall be only too glad to do all in our power to meet such requests, feeling assured that the very best advertisement of Ceylon, its planters and industries is offered in what is familiarly known as the *T. A.* American and English merchants and editors alike express surprise at the amount of valuable information given in its columns, which afford them a new idea of the enterprise and importance of Ceylon.

We are not at all blind, however, to the great room for improvement which exists in this monthly periodical. Indeed, if praise has been freely given, blame has not been wanting. From the West Indies, there has latterly come a cry:—"You give us too much about tea in your recent issues: we want more on the products suited to this division of the tropics;" from Southern India we have an indignant planter writing about the absence of information respecting "coffee," which he says seems to have fallen out of notice altogether; while one or two Ceylon planting friends have been saying, there is too much "reprint" from the columns of the "Observer," or rather that they would prefer to see a good deal respecting practical planting subjects now given in the daily paper, only in the *T. A.* Now the complaint in respect of "reprint" is rather unreasonable, because we think it will be found that of the 80 to 90 close type pages given in each month's *T. A.* more than one-half is of matter which is found neither in the "Observer" nor any other local journal, while it must be remembered in respect of "reprint" that one of the special objects in starting the monthly was to save daily readers the trouble of cutting out and preserving useful planting and horticultural information of permanent value, as so many of them had been previously in the habit of doing. As time runs on we have no doubt the tendency will be to relegate, more and more, all planting essays and more or less technical papers and reports to the columns of the monthly periodical, so relieving the pages of daily papers to deal more fully and directly with the news of the day and with topics of immediate practical interest. At present the readers of the "T. A." have the assurance that no contribution of special interest to the tropical agriculturist appearing in any of the Ceylon or Indian journals, or indeed in the journals or periodicals of England, America, Australia, etc., is likely to escape notice or quotation for their benefit.

Any further suggestions for increasing the usefulness of the publication we shall be glad to receive and consider. From America we hope to receive regularly valuable information bearing upon sub-tropical cultivation in Mexico and Guatemala, as well as in the border States and the West Indies. The field before us is a wide one; there is no lack of workers or of material: it only remains that all who are interested in the development and improvement of a truly representative Planting and Agricultural Periodical should give us the benefit of their goodwill and experience.

TEA AND CACAO CULTURE FOR NATIVES IN CEYLON AND INDIA.

TEA THE PLANT FOR NATIVES—A PROPOSED TEA FACTORY IN KANDY—A CHANCE FOR GOVERNMENT—IS THE LARGE RETURN PER ACRE IN CEYLON LIKELY TO LAST?—FALLING-OFF ON OLD ESTATES—A MOVABLE LIVE FENCE.

12th Oct. 1884.

It is generally recognized as one of the great advantages of growing tea that it will test the ability of the dishonest native to steal it. Unlike almost every other product we grow, here he is checkmated. He may sharpen his wits as he may, have as consuming a passion for his neighbour's leaf as he has for his cardamoms or coffee, yet I fancy he will ever find a stretch of tea a barren field for his absorbing enterprize.

This being so, I know of no better plant, the cultivation of which among the natives themselves might not be encouraged by Government through a free distribution of seeds and plants. Tea is so easy of cultivation, grows so freely at such extremes of elevation, and is so proof against ill-usage, that it would in every respect suit the Sinhalese with his love of ease and holidays.

As to curing, once get the villagers to take the cultivation up, and all over the country there would arise tea factories where the smallest quantities of leaf would be freely bought at a cash price, and cured there under skilled supervision. This system obtains in China, and why not here?

When cacao was seriously taken up and proved a power, the Government Agents and other officials used their best endeavours to induce the natives to plant it, and with considerable success. But the curing of the cacao bean is a difficult matter wanting care, as the quantities of mouldy, badly-fermented nibs which come into the market from native gardens too plainly show. In regard to tea, however, the villagers would very soon learn what to pluck, and, as the green leaf can be carried a considerable distance without harm, all anxiety about curing would cease, and the ready cash system at the factory would suit the buyer as well as the seller. He would have a constant stream of regular customers, and through them cause a free flow of capital into the smallest villages.

It was only the other day that I heard that an enquiry was afloat as to the probable success of a tea factory in Kandy. Had there been encouragement enough, the scheme would doubtless have gone on; but, to insure a paying concern, it wanted a large constituency of small native tea growers, which at present do not exist. The native is very poor it is said, and it appears to me

that there is a chance here for the Government, by a free distribution of seed and plants, to assist them to assist themselves. Factories can't be expected to spring up before the plant, but let the want be once felt, and there will always be enterprize and capital to meet it. Of course many estates are prepared to buy green leaf now, but there are districts where such facilities do not exist, and it is more in reference to those districts I am writing.

Is there truth in the constant croak of our Indian rivals that the large outturn of tea per acre here is not likely to be maintained? I have heard it said that some of the old places are not doing well this year, nor looking so either, and that the falling-off in profits is very serious. Yet this much must be added, that, even at the reduced figures given, the thing was handsome enough. It would be difficult, I fear, to get anything like reliable statistics of a retrograde character: no man wants to depreciate his own property, and an exceptional year such as this has been is not after all a just test as to what old tea may do again in a normal season.

Did you ever hear of a movable live fence? I was hearing of a native dodge with this as its aim and whereby a covetous neighbour may encroach little by little keeping a live fence growing all the time. The plant is the common trumpet-flower, or datura, freely used to mark boundaries, and the system carried out is to give one of the stems a cut, let it fall over into your neighbour's ground, put a stone on the top of it, a foot or two in from the boundary, and by and bye it will take root there. When it has begun to grow, come along quietly with a mamotic, uproot the parent plant, leave the new one growing, and the ground is gained. What a wealth of device there is in the native mind! and how desirable it is that less gifted people should be in a state of preparedness to meet it!

PEPPER CORN.

PLANTING EXPERIMENTS ON A "LOW-COUNTRY" ESTATE IN CEYLON.

COMPARATIVE FAILURE OF LIBERIAN COFFEE—APPARENT TOTAL FAILURE OF CACAO—VARIOUS ENEMIES OF THE CACAO PLANT—WIND, DROUGHT, WEEDS AND WASH—GROWTH OF JAK, KAPOK, AND PEPPER—CURIOUS ROCKS—GEOLOGICAL FORMATION—PROBABLE SUCCESS OF TEA—GOOD GROWTH—DANGER OF TEA BEING OVERDONE—WANT OF WATER-POWER—INDIARUBBER—BAMBOO—PINEAPPLES—LABOR—NATIVE BULLOCKS—KEPPETIYA—A ROCK FOR A FINE VIEW—RATAN PALMS.

I secured 124 acres of land in Siyane (formerly *Cina* !) Korale West, at the period when all believed in the gigantic coffee of Liberia, feeling confident, naturally enough, that its great leathery leaves would resist the fungus which had proved so fatal to the Arabian or rather Abyssinian species. I also contemplated experiments with cacao, cardamoms and tropical products generally, with the resolution, which has been most amply fulfilled, of letting the public have the benefit of my experience whether successful or otherwise. It has been largely "otherwise" until now that tea has been tried. That truly cosmopolitan plant promises, in the low-country as in the high, to compensate for losses by coffee and other products. Not that Liberian coffee on Dumbarton has been an entire failure. There are considerable expanses of the younger trees, than which nothing could look more fresh and flourishing, while some of the older trees, after having been repeatedly denuded by heavy crop-bearing and attacks of *Hemileia vastatrix*, are clothed in pristine magnificence of foliage. Allowing for the ravages of crickets in the early stage of the existence of Liberian coffee, insects generally do not seem much to affect this plant, and, given the right form of trees with plenty of primaries and the absence of the insidious "leaf-disease," Liberian coffee would certainly have been a fair success. It does not seem, however, as if cacao ever could be a success for the special locality. The soil over considerable portions of the estate seems suitable enough, and in sheltered nooks, amidst the rocks and boulders, there are still some fine trees. A good many of the fruits even on these, however, are black, and, on being broken open, reveal colonies of larvæ. The majority in the open had their foliage periodically torn to pieces by the monsoon winds, and, when, in calm weather, a fresh crop of succulent leaves appeared, they were devoured by a variety of biting and sucking bugs. *Helopeltis Antonii* has never, as yet, been identified in any stage, but it is impossible to conceive that he could exceed in destructiveness a maggot which works under a conical cover, for all the world like a limpet, only that the leaf-limpet moves readily about on the surface of the leaf, out of which he sucks the life blood. This destructive insect is I believe, the grub of *Aprata Thwaitesii*, Moore What with this and other insects preying on the leaves, when the wind was not tearing the foliage into shreds, it was no wonder that many of the cacao plants succumbed to the drought of 1884, quite unexampled in severity as it was since 1879. Young coconut palms all around the region looked always so fresh and green, that the violence of the wind was as much a surprise as the amount of wash. For multitudinous weeds difficult of eradication we were somewhat prepared. They require attention in proportion to the forcing nature of the lowcountry climate. Until the jungle was cleared away no one could have supposed that the rock features in the centre of the land were so high and steep:—the highest point 300 feet above the lowest on the estate and 400 feet above sea level. Monsoon rainstorms striking on the summit rocks rush down with violence which could not have been anticipated. The nature of some portions of the surface soil is such,—almost pure humus,—that drains are not so successful here as upcountry in preventing denudation. The climate, too, is far less favourable for planting operations than that of the higher regions in which I am interested, so that the "failures" we have had to deplore on Dumbarton of African palms, nutmegs, cloves, and cardamoms are comparable to those of Beau Brummell with his neckerchiefs. Jak trees grow splendidly (one tree has borne fruit in its fourth year!) and kapok (tree-cotton) promises well. So does pepper, for which the trees named form good supports, as do the perfectly perpendicular faces of rocks. Curiously enough, the pepper vines refuse to grow not only on flat rock surfaces but also on those which incline from the perpendicular. We have plenty of perpendicular masses and columns for this useful plant to cover, so many monument-like columns standing up on one portion of the estate as to justify the term "Necropolis" being applied to it. The shapes of the rocks are most fantastic, boulder being occasionally seen piled above boulder. There is also quite a series of caves, and not only are the rocks weathered, but their perpendicular faces are striated from the effects of temporary water-courses. The stratification is in some cases inverted, and the result of this and of the weathering away of the softer veins is occasionally very curious: a great sheet stands separated some inches from the perpendicular parent rock, and this sheet, on being struck, gives forth a sound as if it were a giant granite gong. I have seldom seen gneiss in Ceylon so granitic in composition as many masses here are, and certainly never saw such a preponderance of red colour over the usual grey of our gneiss. The colour is, I feel pretty confident, due to the large proportion of felspar

crystals in the rock. Many of the weathered boulders are quite red to the eye on the surface. Hand specimens do not show the red quite so vividly, but I believe polished blocks would bear a considerable resemblance to red Aberdeen granite. The colours vary from those of porphyry to the tints of sienite. The estate stands about the centre of a rocky ridge, which is very conspicuous on the right going up, between Mahara and Henaratgoda. I have not the slightest doubt that far back in the geologic ages this ridge, which runs northwards beyond "the tropical gardens" at Henaratgoda, was an important range of the mountain system of Ceylon, the mountains being gradually disintegrated and degraded by the action of sun, wind and rain, before which the felspathic portions especially gave way. The result is a soil not particularly rich but fairly good, where the metamorphic process has not ended in a more or less solid cabook (laterite) subsoil. There is a considerable portion of cabook gravel mixed with the light-coloured soil, and but for the evidence of my senses, to which the metamorphic process is apparent, I should feel the greatest difficulty in believing that the dull dirty-looking laterite pebbles owed their origin to the beautiful glancing crystals of felspar and mica, which shine so beautifully in a fractured piece of the solid rock. Looking at the large proportion of felspar in the rocks from which the soil is derived, there can be no lack of potash, but probably here, as in most other parts of Ceylon, phosphates are not superabundant. With railway carriage so close at hand, these can be added if, as I feel convinced, tea is to be in this neighbourhood, a great success. We measured a plant which at eighteen months in the field had attained a height of 5 feet, 9 inches and after a copious shower of rain during the night the well-established tea plants of a year to a year and a half old looked quite luxuriant. A companion familiar with the growth of tea at an altitude of more than five thousand feet higher up was amazed as well as pleased at what he saw, and the conclusion was that no time was to be lost in making preparations for gathering and preparing the "flushes" which will be rapidly succeeding each other some six months hence on the bushes which will be then two years old,—or two-and-a-half as our Indian friends calculate, counting from germination in the nursery. I ought to mention that an experiment by a neighbour had previously proved that tea, as far as ready and luxuriant growth is concerned, would be a success in this corner of the Siyane Korale. But my neighbour holds his hand from further extensions from the not unreasonable apprehension that tea will be overdone. No doubt there is danger of such a result, and we have the "dreadful example" of cinchona bark before our eyes. But tea is a beverage daily advancing in favour and consumption; and, if it comes to a question of competition with not only China and Japan but India, all the probabilities are that the Ceylon leaf, with its fair amount of strength and its peculiarly delicate aroma, will assert a good position for itself against all comers. So I mean to go ahead with tea at 100 feet to 400 above sea-level as well as at 4,650 to 6,000 feet above sea-level, hoping to be able, in due time, to announce success in each case varying only in degree. Unfortunately there is no water-power for a wheel in the lowcountry place, so that, when we have 100 acres in full bearing and get beyond the stage of hand-pulpers and choolas (furnaces), steam-power will have to be resorted to. The interval will not be long in this forcing climate, for, notwithstanding the unfavourable planting weather which has prevailed for a couple of years back, fully 100,000 plants are already established, and this number we hope to double, perhaps treble on the 100 acres available, excluding rock and other products. Those other products include india-rubber trees and the bamboo. In the former we have largely lost faith, as far as our locality is concerned, while *Bambusa arundinacea*, although it grows readily and forms excellent tall and close shelter belts, is comparable to the Turk who

"Bears no brother near the throne."

Nothing seems able to grow within a certain distance of the bamboo monopolizers. Pinecapples grow readily and would be valuable for fibre as well as food, could the fruits be preserved from thieves, and could the long leaves be cheaply converted into fibre. But our Sinhalese neighbours as well as their cattle are given to stray beyond their own precincts, regardless of the laws of *meum et tuum*. In opening a bit of land in the lowcountry, I cherished the hope of giving employment to the poorer Sinhalese around. But we found, as a matter of experience, that, while our richer native neighbours were speculating on an early transference of our land to them, the labouring classes were so exorbitant in their demands that Tamil labourers had to be employed. This is certainly a most unexpected result, and one neither anticipated nor desired by us. We travelled 7½ miles from the Henaratgoda railway station in two very small bullock-hackeries, drawn by very small Sinhalese bullocks. The animal which drew the hackery in which my companion and I deposited ourselves (our effects being in another hackery) was so diminutive, that we hesitated to trust ourselves to his strength for the journey. But we were carried on and back next day at the rate of four miles an hour, steadily and well. Our driver was a bright intelligent Sinhalese lad, who conversed fluently with my companion in Tamil. He volunteered the opinion that my land was good and that any success would be certain if I only grew coconuts. I objected that they were overdone and liable to be stolen. He said two watchers at R10 per mensem each would obviate this objection. He flattered us by saying he would like to take an employment under us. A cart-load of sweet smelling leafy twigs passing us, we learned from him that the plant was *keppetiya* and that it was used as a special shade and manure for betel-vines. The detached rocks of the ridge were scattered all along our road, and we noticed a good many rock-pineapples growing where there was some soil on the rocks and euphorbias where there was scarcely any.

THE NORTHERN TERRITORY OF SOUTH AUSTRALIA seems to be by no means an earthly paradise, judging from the accounts of murders by natives which have recently taken place there and details of which are given in the latest Australian papers to hand. One of these outrages, we see, took place near Rum Jungle, Poett's land, where a former murder was also committed Mr. Poett may therefore congratulate himself, that, though his planting company has had to be wound up, he has not lost his life at the hands of the blacks.

COFFEE IN JAVA.—In Mid Java many coffee estates within the province of Surakarta, owing to the ravages of leaf disease, will hardly yield a tenth part of the crop secured last year, there being every prospect of the coffee export from Java this year showing a considerable falling off in consequence. Mr. Van Delden Laerne's report on coffee-growing in Brazil is expected to take up about 500 pages of print divided into 12 chapters. To the report there will be appended two large maps of the coffee area in Brazil, namely, a geological one prepared at Mr. Laerne's request by Professor Derby, a geologist at Rio, and a physical one showing the coffee-growing districts and railway lines open for traffic therein on the 1st January 1884.—*Straits Times*, Oct. 2nd.

GROWTH OF TEA AND OTHER TREES AT AN ALTITUDE OF FROM 4,800 TO 6,000 FEET IN UPPER LINDULA, CEYLON.

EFFECT OF RAIN AFTER DROUGHT—MEASUREMENTS OF SEED-BEARING TEA BUSHES—DISTANCES FOR PLANTING TEA—PICKING AND PRUNING OF SIDE BRANCHES—TALL TEA TREES—GROWTH OF BLUE GUMS—THE "GUM DISEASE"—TIMBER TREES—FAVOURABLE WEATHER FOR FLUSHING—OUTTURN—PRUNING—RAINFALL—*Helopeltis Antonii* ON THE TEA, BUT LITTLE DAMAGE DONE.

LINDULA, 14th Oct.

The genial rains which have recently succeeded the long drought have brought out tea and other vegetation wonderfully, and the flush on pruned tea bushes can almost "be seen growing." The soil is a good tea soil, but the altitude is what a few years ago would be regarded as extreme. Our insular position, contiguity to the equator and generally regular alternation of tropical heat and moisture were forgotten. On this estate (Abbotsford) tea promises to compensate for all disappointment in the case of Arabian coffee (we have not had much to complain of in regard to cinchona from first to last), and yesterday measurements were taken of unpruned tea bushes reserved for seed-bearing and of pruned plants operated on so as to promote lateral growth and surface foliage, those present being the proprietors (Messrs. A. M. Ferguson, senior and junior), Mr. John Hampton, Mr. W. B. Lamont and Mr. Max Wright. The figures recorded by Mr. A. M. Ferguson, junior, are as follows :—

TEA BUSHES.

Lower Estate.—Slightly less because side branches growing *upwards* now.

8 yrs. old — All unpruned.

Giant tea bush	...	26 ft. × 29 × 24-6
Big bush near	...	25 × 22-5
„ „	...	14 × 14-6

Circumference of stem 2 ft. 3 in.; 9 in. diameter

Another tree height 23-6; circumference of stem at 3 ft. from ground 18 in.; 6 in. diam.

Another circumference of stem 2 ft. 3½ in.

7 & 8 yrs. old. — All pruned.

9 ft. × 8-2; circumference		26-9
9-6 × 9-8	„	28-9
8-6 × 8-3	„	25
11-2 × 12-6	...	16-2

one bush. one surface.

16-2 one surface, by Cymru Gap.

7-9 × 7-9. Circumference 23½ ft.

Upper Estate.—At 6,000 ft., 2 yrs. old 4 ft. diam.

At 5,900 ft., 2 „ 3-6

3 „ 5-6 × 5-6

Grevillea 11 yrs. old, circumference of stem 4 ft. 2 in.; height about 50 ft.; diameter 1-5.

Gum 8 yrs. old, circumference of stem 5 ft. 2 in. height about 100 ft.; diameter 1-9.

The unpruned trees are all retained for seed-bearing; those pruned are all cut so as to compel them to spread horizontally and yield the largest possible quantity of "flush." Some of the trees are exceptional, but many of the pruned trees of similar age show similar dimensions. Here, as elsewhere, there is considerable disparity of growth in plants, but generally the ground is being so rapidly covered that I have felt compelled to give up the planting distance of 3′ × 3′ on which I insisted ever since returning from Darjiling in 1876, in favour of 3′ × 4′. That up here. What, then was my amazement, to hear a few days ago from one of the best and most reliable authorities, that on the lowcountry tea estates in Ceylon, closer and closer planting is being adopted, until recently an experienced superintendent has adopted 3′ × 2½′! Either the growth must be chiefly upwards in such cases, or the system of picking and pruning side branches must be in vogue. The late Mr. Cameron practised and recommended that system, but, whether rightly or wrongly, the superintendent of this estate now holds, after full experience, that he would as soon cut his best friends as cut away branches growing out sideways from his tea plants. He is doing all he can, and with much success, to obviate the evil produced by previous side-picking and pruning; and the trees are in most cases so rapidly meeting, that the problem is how the pickers and cultivators are to make their way between plants put down 3′ × 4′. If that is close enough at 5,000 to 6,000 ft., it would seem as if 4′ × 5′ would be a good distance at anything below 1,000 or even 2,000 feet; but of course, each planter must finally decide on the results of his own experience. The height of a handsome tea bush with a nutmeg-tree habit of growth, on the side of a path, is given at 23 feet 3 inches; but amongst trees of the original 1874 nursery, allowed to grow up close together, there must be specimens about 30 feet high, actual measurement some years ago having given 27 feet. In *lateral* growth, the giant tea tree seems the largest as yet described. The superintendent specially rejoices in the wide surfaces of his 2 and 3 years old plants, which had never been picked or cut at the sides, except to get rid of a straggling or superfluous branch. The height of some of the blue gums planted closely in 1876, estimated at 100 feet, took even us by surprise. There promises to be a reproduction on a small scale of the grand scene at Fernshaw in Victoria, where the highest trees in the world shoot up close together and branchless as far as the eye can reach, like pipes of a vast organ. Our tall gums are at 4,800 feet, near the site of "the old bungalow," and were never affected by the "gum disease" which in 1882 was so virulent at the higher elevations. As ornamental and timber trees, however, we value the grevilleas more than the gums, while the toon (*Cedrela toona*) promises to flourish here, no insect having yet attacked the few fine specimens raised from seed received from the Dehra Dun. The Norfolk Island Pine, *Araucaria Bidwillii*, with cypresses, junipers, and other plants of various lands, do fairly well up here. But surely, no timber tree in the world can excel the blue gum for growth with 100 feet in 8 years! Tea, however, requires shelter trees less than any plant of economic value we know of, and we mean in future to confine attention to *Grevillea robusta* and the red cedar (toon), having a good deal of indigenous timber trees left in belts.

The weather is all that could be desired for tea flushing, and 1,700 lb. of dry tea were made here last week from 6,944 lb. of green leaf. The quantity would be much larger but for the discretion which the superintendent felt bound to exercise of pruning some of his fields in May and other months most productive of flush. This year pruning has gone on, and will go on all over the seasons. In future, it is hoped, to concentrate the operation into the winter months. Notwithstanding the qualifying effects of the pruning, there is every prospect of the estimate of 500 to 600 lb. per acre being realized. Of course, some difference may be made by rains in the north-east monsoon, heavy in proportion to the deficiency in the south-west. As yet there is no sign of an abnormally rainy monsoon, the rainfall this month having been on the 1st, 0·13 inches; none on the 2nd and 3rd. On the 4th, 0·25; 5th, 0·28; 6th, 0·56; 7th, 0·16; 8th, 0·28; 9th, 0·02; 10th, 0·67; 11th, 0·01; 12th, 0·13 and 13th, 1·36. The rain has fallen chiefly at night and there has been good, genial sun-heat during daylight.

P.S.—The estate has suffered little from insects, but I regret to say that a careful search has resulted in the discovery of the undoubted presence of immature *helopeltis*. I have assured myself of the identity

of the bug under the microscope. We could not hope to escape from this pest, but let us hope its effects may be small and unimportant. So far, though it has been a year on this estate, it has done no appreciable damage.

TEA CULTURE AND PROFITS IN CEYLON.

The romance of Tea Cultivation in Lanka has already commenced. Old K.'s C. B. now retired on well-earned competencies—alas that there are so few comparatively out of the long roll of Ceylon's planting worthies—will please understand that not in its palmiest days has coffee beaten the crops and the profits which have already accrued from TEA. The romance of coffee-planting circles around the time when the choice Hantane, Deltota, Elkaduwa, Kelebokka and Rangela plantations were worked as veritable gold mines,—when the clusters of cherries could never be all picked, but to tread on coffee was the normal experience of superintendents and coolies,—when for instance, on an estate (1892 acres of Hantane forest !) bought in 1837, there were 350 acres planted by 31st December 1841 with stores, machinery, &c., at a total expenditure of £6,938 including purchase of land; while the receipts up to the same date including the crop of 2,000 cwt. of coffee gathered off 200 acres (50 only in full bearing) was £11,639; and the estimate was 3,000 cwt. off 250 acres and a steady return of 5,000 cwt. (no doubt realized for a considerable time) off the 350 acres when in full bearing!

Tea-planting has not yet reached these noble proportions; but then considering the extra work in the tea-house and the margin for larger profits if a place is properly worked, 100 or 120 acres of tea ought to be considered equal to 200 of coffee. One of the oldest of Indian Tea Garden proprietors told us he preferred to have nothing over 50 acres under one manager's care and to aim at working this up to a steady yield of 8 and even 10 maunds per acre through constant and liberal cultivation and unremitting attention. And certainly, already in Ceylon there is encouragement to do full justice to the land yielding tea crops.

There is Mariawatte "tea garden" of which every old coffee-planter can form some idea since it is situated on historic ground near to the first coffee plantation (Sinnapittia) opened in Ceylon and by no means on primeval forestland. As much as 1,400 lb. or close on *seventeen maunds* of made-tea per acre have been gathered over choice portions of this "garden" and 100 acres planted 4 by 4 feet (with a good many vacancies) have yielded close on 100,000 lb. of made-tea or nearly twelve maunds per acre! A return of £25 an acre is a moderate estimate of the year's profit under such circumstances; and indeed, we are aware that one of the fortunate proprietors has been astonishing old Ceylon men at home already by a sight of the figures representing moderate outlay on, and high receipts from Mariawatte—figures which were never eclipsed in the best days of coffee.

"One swallow does not make a summer," but Mariawatte by no means stands alone. There is the case of 100 acres of young tea in a remote, unsuccessful and most unpopular coffee district with the cultivation of which a well-known London house, on the advice of their local agent, would have nothing to do when it fell into their hands. Rather it was offered back to the debtor for one-seventh of his estimate of its value. Purchasing it for £700 cash, the 100-acres garden was at once leased for half the amount, and now we are creditably informed, that it brings an income to the fortunate owner of R5,000 to R6,000 per annum apart from the lessee's profits.

Yet again in the same district and in the midst of a country which has broken the purses, if not the hearts, of not a few coffee estate owners, agents and managers, we have one of the most flourishing and profitable tea plantations in Ceylon. The reputation and the fortune of a young member of our mercantile community may well be said to have been made in this case. His older compeers hung back, or shook their heads over the risks associated with tea, and allowed a garden valued at R120,000 to sell for "a mere song" on the death of the owner and the peremptory winding up of his estate. The gentleman who happily invested, would not today take probably ten times what he paid about a year ago for his 350 acre of tea and large extent of reserve forest land. The crops and profits have already been proved to be abundant, and the climate and growth of leaf are all that could be desired.

On other estates in the Morawak Korale besides Anningkande and Campden Hill, the cultivation of tea is certain to be a great success. The Craven, Enselwatte and many other familiar names of old coffee plantations are in a fair way to come into notice as prosperous tea gardens and no less in the adjoining Kukulu Korale are there areas under tea, the growth of which is deemed perfection.

One of the earliest plantings of tea in Ceylon was on Closenberg estate, Morawak Korle, by its spirited proprietors in the pioneering days of the district. The seed was among the finest ever imported into Ceylon and a part was utilized on land belonging to the same owner near Nuwara Eliya. The enterprize was however not then proceeded with, and it is only now that Capt. Bayley has begun to take an active interest in the suitableness of his Pedro property for tea. Five acres under this plant have been cropped since December last, the plucked leaf being sold to a local factory and carefully weighed with the following result—which it is worth giving in detail because although the 'romance' here has yet to come, there is ample encouragement in the figures for a beginning at a high elevation :—

	Plucked leaf lb.
Dec.	851
July	541
Feb.	940
March	1,568
April	784
May	986
June	1,502
July	373
Aug.	711
Sept.	936
Plucked leaf	...9,192 lb.
Made-tea	...2,298 lb.

Ten per cent was allowed off the weighing when there happened to be a shower. The result it will be seen was equal to a plucking of over 229 lb. per month. The actual number of tea plants plucked was 14,125, which at 4 by 4 feet would give 5 1-5th acres. The crop of made-tea was therefore equal to 528 lb. per acre for twelve months, and if the place were planted 4 by 3 feet, it is possible that as much as 672 lb. might be obtained or 8 maunds per acre. Taking these as outside estimates even, for so high an elevation as Nuwara Eliya where the flavour of the leaf ought to be exceptionally good, they are most encouraging.

But from no quarter do we have other than good news of tea; and from Matale on the one side to Uva on the other, the utmost activity prevails in the forming of nurseries and the planting out of the product which is soon to be the King of Ceylon's Agricultural Enterprise. Has Sir Arthur Gordon asked himself or his Executive Council

what they ought to do to encourage the people of the land to cultivate a plant which has so evidently found its home in Ceylon? Surely the Agents and Headmen might be made the medium of distributing tea seed and instructions to the villagers to secure a start in all the districts suitable for the growth by Sinhalese and Tamils. What will be said in England—if a collapse of the China tea trade concentrates attention on India and Ceylon—when it is made known that while 50,000 acres were planted with tea in this island by private agency, chiefly colonists, its Paternal Government was so fully engaged in developing a grand Irrigation policy for the future, that no notice was taken of an industry which is clearly destined to become the most important in our Agricultural record and which will probably exercise a greater influence on the material improvement of the people, and on the general revenue of the Government, than all the local grain cultivation. If the Sinhalese and Tamils learn to grow tea freely, in addition to their palm and fruit trees, they will soon in nearly every populous or occupied district, have plenty of means to indulge in the necessaries and even luxuries of their most prosperous days. They will understand what it is to sell in the dearest and buy in the cheapest market.

The romance of our tea cultivation will indeed become a story of world-wide interest, should the Chinese lose even a single season! Very speedily would the estimated maximum of 150,000 acres (of old if not new land) in estates' be planted up and capital flow to Ceylon for investment. But, even without a Chinese blockade, our tea industry is bound to advance steadily and the encouragement to plant (carefully and judiciously) is as great as could be desired.

THE INDIAN TEA INDUSTRY: A POPULAR RÉSUMÉ ON PRODUCTION, CONSUMPTION, THE PLANTER'S LIFE AND PROSPECTS.

In the last number of *Punch* Mr. Linley Sambourne depicts India in the form of a homely barn-door fowl sitting expectantly on a tea-chest, while the epauletted Gallic cock and his peacock-tailed rival of China breed tear one another to pieces. When the Crimean war took place India first found that she could supply Europe with linseed and jute. The American war gave an immense stimulus to the Indian cotton trade, and the last war between Russia and Turkey was not without its influence in creating the trade in Indian wheat. Mr. *Punch*'s artist has happily hit off the idea that the wars of other nations are India's opportunity, and that this country may step in as chief purveyor of another important staple of hostilities between France and China are carried to an extreme. Although Bombay is the only presidency in which the tea plant has not found a home, our prosperity is very closely concerned with that of the rest of India, and at this juncture it will probably interest many of our readers to have some details of the history of the tea trade placed before them. Indigenous tea was first discovered in Assam in 1830, but the Indian tea-plant of commerce is chiefly a hybrid between the indigenous and China varieties. Tea planting was commenced in India by the Assam Company in 1840, and it was not until ten years later that the industry was taken up by others. For twenty years afterwards cultivation expanded slowly, and we find that in 1870 the imports into England, to which market nearly the whole trade was directed, amounted to only ten millions of pounds. Since then, however, the increase has been rapid, as the yield of 1883 amounted to 59,215,763 lb., while that of 1884 is estimated at 66,664,359 lb. There is ample room for further expansion, as the United Kingdom consumes 165,000,000 lb. of tea, the United States and Canada 80,000,000 lb., and Australia about 15,000,000 lb., while the local Indian market is still largely supplied by China. In 1878 the consumption of tea per head in England and Australia was as follows:—United Kingdom 4·66 lb., Victoria 6·92 lb., N. S. Wales 7·53 lb., Queensland 9·16 lb., New Zealand 11·05 lb. The rough open air life of the colonies thus appears to make their inhabitants the largest tea drinkers in the world. Indian tea has not hitherto made much way in any country except England, but there its excellent qualities which are so thoroughly appreciated among ourselves are enabling it gradually to supplant the produce of China. We annex the approximate figures from 1878 to 1882 in millions of pounds:—

	1878.	1879.	1880.	1881.	1882.
China...	121	125	115	111	110
India....	37	35	44	49	54
Total...	158	160	159	160	164

It thus appears that although the total consumption of tea increases but slowly, that of Indian is as steadily growing as that of China is diminishing. No very rapid change is possible, as the tea plant takes quite four years to arrive at maturity, but the position of the Indian planting community will be much improved and the prospect of increased export in future years greatly enhanced if the war which has recently broken out effects any stoppage of shipment from China.

Two or three new books on tea-cultivation are now before us, and they do not present a very pleasant idea of a planter's life. Colonel Money, a high authority, gives it as his opinion that "a really pleasant climate to live in cannot be a good one for tea," and Mr. Barker, in his "Tea Planter's Life in Assam," says, that on the whole "a planter's life is not a happy one." Many, however, who are engaged in sedentary occupations in big cities will look at the picture he displays much more wistfully than Mr. Barker does. It is Mr. Barker's business to depict with a somewhat sketchy pen the life of a planter in Assam, that vast but little-known province in the valley of the Brahmapootra, which has been redeemed from primeval jungle by English enterprise and is now the principle source of supply of Indian tea. He begins with the well-worn subject of the overland route with its reminiscences of diving boys at Aden and snake men at Madras, while a whole chapter is devoted to the novelties which are disclosed to the stranger on arriving in Calcutta. The journey thence by rail or river steamer has also a chapter to itself, and tea only puts in an appearance far on the book. The Assamese are singularly independent, even if they are not, as Mr. Barker says, "inconceivably and supremely happy." They owe allegiance to no one but their Gossain. They cultivate their own little plot, and utterly decline to work for the tea planter, who is entirely dependent upon imported labour. The planter, at all events in Assam, has to make up his mind to rough it. He lives for the most part in a bungalow of wood, thatch and mud, generally divided into three rooms, and sufficiently uncomfortable to send him on to the verandah for the chief portion of his time. From the want of dak bungalows, every private bungalow is an asylum for the traveller, and a "more hospitable set of men than Assam planters does not exist." A manager of a tea-garden must, Mr. Barker tells us, be "a rather out of the ordinary sort of man. To be of any use he must be of strict integrity in order to gain the confidence of his employers; sober, business-like, a good accountant, not easily ruffled, handy at carpentering and engineering know something about soil, and have a smattering of information on all subjects; or, to put it concisely, he must be a veritable jack-of-all trades." We should judge from Mr. Barker's book that he is

himself singularly deficient in all these qualities, and that he does better work at the desk than in the garden. The difficulties of locomotion in Assam are aptly described in the sentence that "to get to the river in the rainy season often requires the combined assistance of a buggy, a pony, an elephant and a native boat." It should be remembered that the whole province lies close to the Brahmapootra. The want of society will at first be badly felt. Of sport Mr. Barker writes that a man engaged in tea-planting having his time fully occupied from the first of January to the thirty-first of December has little opportunity for this diversion. But it is plain that he has as little taste for sport as for tea-planting, for he actually recommends his readers to go to the Geological Gardens in London to see tigers, elephants, buffaloes and rhinoceros, and considers it a misnomer to call the shooting of these huge animals sport.

Leaving his book aside for the moment we will give a short practical account of the production of Indian tea. The work of a planter after obtaining his land commences with clearing the ground of timber, which is usually done by contract with Assamese at so much per acre. A small portion of the wood being reserved for building purposes, the rest is all turned into charcoal and stored for use in the factory that is to be. The soil is then dressed with the hoe and the seed or seedlings put in where they are to remain. For two years afterwards the planter lives upon hope, carefully cultivating his young plants and preparing the various buildings requisite for his own and his coolies' residence, and for the manufacture of the leaf when the bushes shall have grown strong enough to bear the strain of "plucking." It is not, however, before the fourth year, and often later, that the yield is sufficient to repay the cost of cultivation. The picking of tea is almost entirely done by women, the fingers of the male cooly being too clumsy for this operation. Both skill and experience are required in taking off the leaf, because in order to secure a maximum out-turn the plant has to be kept in active growth from March to November, which can only be accomplished by delicate handling. When each labourer has filled her basket the green leaves are taken to the factory and weighed, after which they are thinly spread out for a few hours to soften or wither, as it is technically called, in order that they may undergo the process of rolling without breaking. In former days rolling was euphemistically said to be done by hand, but it was really done by the elbows or ribs, and knees and feet, as the hands of a very sudoriferous set of coolies, and this method of manufacture still prevails in China. In all modern Indian factories, however, the leaf after being withered is placed upon a rolling-machine and finished in the cleanliest manner possible. After having a twist put on it by the roller the leaf is left to ferment until it changes colour, when it is promptly transferred to trays and fired either over an open charcoal fire or in a newly patented "tea drier." This done, the leaf which yesterday was growing on the trees has already become the tea of commerce with which all are familiar, and nothing remains but to sort it into Souchong, Pekoe Souchong, Pekoe, &c., pack and send it to market. And, as we have shown above, the English market now absorbs almost half as much tea from India as it does from China, and the consumption of Indian tea is steadily increasing every year. It remains to be seen whether the Chinese war will really give it a sudden impetus.—*Times of India.*

DISTILLATION OF ESSENTIAL OILS.—A correspondent writes :—"I shall be obliged if you will let me know where I am most likely to get good and correct information regarding the mode of distilling oil from lemon and other grasses and the most approved style of store for drying purposes." Our correspondent will find some information on this subject in Vol. II of the *Tropical Agriculturist*, but we should be glad to hear from anyone engaged in distillation.

THE WILLESDEN WATERPROOF PAPER.—Has this material been practically tried in Ceylon? The *British Trade Journal*, in a notice of the Amsterdam Exhibition states :—The Willesden Waterproof Paper Company are making the most extensive display of their paper which has ever been seen. The building for the British Commission is wholly constructed of it, and some distance from this is a complete set of Dutch farmhouse buildings in full size, also made of Willesden paper. Near this are various forms of Willesden paper stack-roofs, arranged for raising and lowering, one being of the pentagonal form usual in Holland. Pipes 30 feet long, formed of sheets of Willesden paper simply rolled together by hand, and adapted to draining and water-carrying purposes, are also shown, water being pumped through them. It is stated that several years may elapse without the slightest effect being produced upon this paper by moisture, and the down-pours of rain upon the farm buildings here seem to warrant this statement. The advantages of easy transport, construction, and repair are so great that the public should soon have confidence in houses, tubes, boats, etc., of the Willesden material.

HELOPELTIS ANTONII : NO EVIDENCE THAT IT HAS YET ATTACKED TEA IN CEYLON.—Under the circumstances, we feel sure Dr. Trimen will not object to our publication of a letter he has addressed to the superintendent of Abbotsford :—"I am glad to have your note and the specimens, but the latter are not at all conclusive. In my opinion, they give no sure evidence that *Helopeltis* has been at work—a hundred other bugs could make such holes. Though *Helopeltis* is difficult to detect, it can *always be found* ; since, being wingless till the adult stage, it cannot leave the tree on which it is hatched, and is slow comparatively in its movements in its immature stages. The *cinchona* you send, I can, I think, say with certainty, does not owe its damage to *Helopeltis*, but to some quite different and less formidable sucking insect. I am glad to hear so good an account of tea and cinchona with you. It is certainly a very different season from two years' back when I paid you a visit." No trace of the insect, mature or immature, has been seen on Abbotsford : only leaves were seen with marks, resembling those on engraved leaves in the *Tea Cyclopædia*, said to be made by the tea bug or blight ; but Dr. Trimen sees no evidence of the action of *Helopeltis* in the specimens of leaves sent to him.

ADULTERATION OF TEA IN JAPAN.—The *Japan Weekly Mail* states :—Mr. Miki Soyemori, Superintendent of the Kiyoto Tea Industry Association has, according to the *Fiji Shimpo*, formulated a very serious charge against the foreign tea manufacturers of Kobe. Mr. Miki some time ago inspected the processes by which these foreign firms prepared their teas, and was utterly amazed by what he saw. His account is that Uji tea is mixed with sundry leaves and a green powder is then sifted over the mixture to give it an attractive colour. This "doctored" article is sold abroad as pure Uji tea, at an extravagant price, and naturally the reputation and sale of Japanese tea is much injured. The iniquity of this proceeding struck Mr. Miki as rendering the matter worthy of most serious consideration, and he lost no time in calling a meeting of his Association. The meeting was held on the 27th ult. and it was resolved that a report on the subject should be presented to the Central Tea Association in Tokiyo with the object of petitioning the Government, through the Tokiyo Association, to take proper steps to remedy the abuse complained of.

CITRONELLA GRASS fields in the neighbourhood of Galle are said to be going out of cultivation, through exhaustion of soil probably; but how is the large and increasing export maintained? There is no doubt a wide extension of the industry in the Matara district. It is said that the grass usually exhausts the soil in about ten years, necessitating a fresh planting on virgin land; the profit is generally deemed to be very small, but with the keener demand of late the margin may be better. The wonder is that men with experience in distilling the citronella and cinnamon oils in the lowcountry do not attempt to utilize the highly scented flowers which grow so luxuriantly in the hill-country, often in considerable expanses—for instance, roses, sweet-scented verbenas, patchouli, geraniums, &c. The experiment is worth making.

ANSELL'S SEPARATING AND WINNOWING MACHINE was tried at the Kollupitiya Mills, Colombo, with satisfactory results. Two chests of Windsor Forest, giving an outturn of 77 lb. unassorted tea, were used, and the working gave :—

No. 1	..	10 Orange.
,, 2	..	23½ Broken Pekoe.
,, 3	..	11½ Pekoe.
,, 4	..	20½ Souchong.
,, 5	..	6½ Congou and Red Leaf.
,, 6	..	5 Fannings.
		77

This shows a very satisfactory proportion (about 56 per cent.) separated of the better sorts, and several experts who were present were much pleased with the result. Ansell's tea Sifter, which we saw at work at Messrs. Lee, Hedges & Co.'s store, Kollupitiya, is at the same time simple and efficient. Our previous experience had been with Jackson's machine, which has given satisfactory results, sorting the tea into four different sizes at the rate of 400 or 500 lb. per hour, while a cooly could only do 100 lb. in a whole working day. Ansell's machine is calculated to sort into five sizes a quantity of tea ranging from 4 to 6 maunds, that is, 320 to 480 lb. per hour. It has the advantage over Jackson's of fanners, by means of which the dust and light stuff is at once separated from the tea-leaf. A portion of a box of Windsor Forest mixed tea was operated on, and it was striking to compare the beautiful tippy broken pekoe which came out at one orifice with the coarse congou which was collected at another. In a factory where large quantities of tea are prepared, such a machine as Ansell's (which amongst sifters holds the place which Jackson's machine does amongst rollers) must be of great use. If the price demanded is one fairly moderate, we cannot doubt there will be a good demand for the patent sorter.

PLANTING NOTES FROM KOTAGHERRY : 6th Oct.—Prospects have brightened considerably during the last few days. Good steady rain seems to have set in, and what remains of our crops may be considered safe, though the proportion of light coffee this year will, I am afraid, be very great. Outturns will be dreadfully short. Many estates had good blossoms, but only those in the best condition have carried their crops through the worst drought we have had for some 16 or 17 years. Still it has hardly been so bad as some ignoramus represented in a local paper, where I saw a statement to the effect that Kotagherry had had no rain for ten months! My gang on the ghaut gives a return of just 17 inches for this year, not counting the fall of the last three days. An estate here was recently valued taking present prices and crops, the profit expected *this season* being put as 10 % of the value. At this rate many of the best estates in Southern India are worth nothing (take the Ouchterlony valley for instance), simply because they will give no profit this season. The valuer was an experienced planter, and I mention it just to show to what depths poor coffee has descended. Tea is beginning to flush well, now the high winds have dropped, than which I know nothing worse for keeping back flush and spoiling it when it does come. Cinchona has stood the drought very fairly on the whole. We are having our yearly try at reducing curing charges. With present prices it is rather too aggravating to pay 50s a ton f. o. b. in cases and to see your Colombo rate of 35s advertised in every *C. O.* Some of our leading planters think of making overtures to a Colombo firm, asking them to set up a branch at Mettapollium, Coimbatore, or Beypore, on a certain number of tons being promised them. Anyone curing at 35s would cut out every curing firm in South India. Labour is cheaper with us, as far as I know, than with you; so why should it not be done? The firms here say they cannot reduce rates and have a profit, and one firm assured me that the Colombo firms would have to raise their rates again. I think it will be the other way, and our friends will have to lower theirs, if they wish to keep their patrons. *Nous verrons.*

THE COCONUT PALM.—The king of low-country products is, of course, coconut. What coffee was to the hill-country coconut is to the seaboard districts. Indeed, it may lay claim to the sovereignty of the whole Island; for the aggregate value of all the varied products of the coconut tree exported cannot, we feel sure, be of greater value than those consumed locally in the shape of food, oil poonac, thatch, coir-goods, fuel, timber and articles of domestic use. [The proportion of local consumption of products of the coconut (as well as of the palmyra) palm must be immensely greater in value than the export.—ED.] If coconuts never gave proprietors the magnificent profits which coffee at one time yielded, they never, on the other hand, involved them in magnificent losses. Not that coconut cultivation has not its enemies, like other products. White-ants and porcupines and wild-pigs are, at times, formidable to young plantations, and so are beetles and lightning to established ones; but history refers to no scourge which ever devastated coconut plantations in the way that *hemileia vastatrix* has ruined coffee estates. No natural laws are violated in its cultivation; for the tree is allowed to grow at its own sweet will, without being hacked and hewed to promote fruitfulness; and Nature makes return in longevity and regular crops. These may further be regarded as the reward of patience, and the subjection of the desire to hasten to be rich. Thus has it come to pass that coconut estates have long been regarded in the light of a safe, if slow, investment, as distinguished from a speculation; but, we fancy, during last year proprietors of estates in full-bearing derived an income from them larger than any other Island product has yielded. The oil shipped up to the 30th ultimo aggregated 424,000 cwt, against 306,000 the previous year, and only 184,000 in the year 1881-82. Not only are the shipments far in excess of those of any previous year, but the prices which have ruled —about £30 a ton on an average—although only about 2-3rds of the figures reached in the fifties—have given satisfactory profits to the grower. It does seem strange that an oil locally produced in abundance at small cost, should be superseded by an imported article brought thousands of miles in secure packages; but it is yet the fact that Kerosine has largely displaced coconut oil, not only in households in towns, but even in many of the villages among natives. Nothing is more common than to see villagers returning to their homes by train or on foot with attractive little Kerosine lamps and a bottle of the cheap oil. For reading, coconut oil is decidedly preferable, as giving a softer and cooler light—it has also the advantage of standing gusts of wind better than its mineral rival—but it cannot be compared in cheapness with the product which the bowels of the earth yield in such plenty in America and Russia. It is not, however, for lighting purposes that coconut oil is chiefly exported, but to be used in the manufacture of soaps and lubricants, and to some extent of candles; and for these the demand will continue.—"Examiner."

HOME-GROWN COFFEE IN QUEENSLAND.

A correspondent sends us the following interesting particulars:—Some years ago I lived at a place where there were over a dozen coffee trees. We had more labourers than there was work for, and to occupy the men the coffee berries were gathered when turning brown. After being quite red like a cherry they were roasted in a pot, in which a little fat was put to keep them from burning. Some of the beans had good coffee kernels, others were empty; the full berries did not roast so soon as the empty ones, and they were sifted and after a time roasted again. We had so many they were put in small barrels and headed up. I had one opened a few days ago, and they were as fresh as when newly put in. It makes good coffee, and any farmer could grow his own coffee. There is too much chaff in this for it to take in the market; but if enough is put in and allowed to infuse it makes nice rich coffee, which no one refuses to drink. I grind it in the corn-crusher at first, and if I wish it finer, I put it through the coffee mill. It only requires to stand longer when coarsely crushed. I found the coffee trees grew best when they were sheltered from the westerly winds, and did not catch the morning sun in winter. If you would like to see the berries I can take you some when I go to town. Where I now live it is too much exposed to all winds to grow coffee, bananas, or cassava.—*Planter and Farmer.*

THE KOLA NUT.

In "A Curious and Exact Account of a Voyage to Congo, in the Years 1666 and 1667. By the R. R. F. F. Michael Angelo of Gattina, and Denis de Carli of Piacenza, Capuchins, and Apostolic Missionaries into the said Kingdom of Congo," of which a translation is given in Vol. I. of Churchill's Collection of Voyages and Travels (1704), there is the following reference to the kola nut:—

One day they brought me a quantity of round Roots like our *Trusses* (in *English Pignuts*), but these grow on Trees and are as big as a Lemmon; opening them, there appear four or five such Nuts red within. To keep them fresh, they put Earth about them; when they will eat of them, they wash them, taste a little of each, and drink of their Water. In eating of them they have a little bitterishness, but the Water drunk after makes them very sweet. In their Language they call them *Colla;* and I having observed that the *Portuguese* made great account of them at *Loanda*, had some sought out, and sent them to those Gentlemen my good Patrons, who in return sent me some Presents come from *Europe.*

In the translation (in the same collection of voyages, Vol. V.) of "A Description of the Coasts of North and South Guinea; and of Ethiopia Inferior, vulgarly Angola," by John Barbot, the following references to the nut are made:—

The *Portuguese* in this country make much use of the fruit *Kola*, resembling a large chestnut in the rainy and winter seasons, of which more hereafter.

The *Cola* is a sort of fruit somewhat resembling a large chestnut, as represented in the figure, which is of the natural bigness. The tree is very tall and large, on which this fruit grows, in clusters, ten or twelve of them together; the outside of it red, with some mixture of blue, and the inside, when cut, violet-colour and brown. It comes once a year, is of a harsh sharp taste, but quenches the thirst and makes water relish so well, that most of the *Blacks* carry it about them, wheresoever they go, frequently chewing, and some eat it all day, but forbear at night, believing it hinders their sleeping. The whole country abounds in this *Cola*, which yields the natives considerable profit, selling it to their neighbours up the inland, who, as some *Blacks* told me, sell it again to a sort of white men, who repair to them at a certain time of the year, and take off great quantities of it. These white men are supposed to be of *Morocco* or *Barbary*, for the *English* of *Bence* Island assured me there was a great quantity carried yearly by land to *Tunis* and *Tripoli* in *Barbary.*

The *Poglow*, which produces the famous fruit *Cola*, is of an indifferent height, the trunk about five or six feet in circumference. The *Cola* is a chestnut, as I have said before, three or four growing together in a rind, each divided from the other by a thin skin. The natives use it much in their sacrifices or offerings to their idols and in their conjurations, and have perpetually some in their mouth, either walking or sitting, to relish water the better, reckoning it very wholesome, as I have said before. The *Portuguese* drive a great trade with it up the country.

The fruit *Kola*, by the inhabitants of the coast called *Boesi*, grows here as in *North-Guinea*, but no so plentifully. The *Europeans* of the coast call it cabbage-fruit. I refer, for a further description of it, to what I have treated thereof in the preceding book, speaking of *Sierra Leone.* The *Blacks* are of opinion here, as well as there, that chewing of it helps to relish water and palm-wine. They do also commonly eat this *Kola* with salt and malaguetta; the sole virtue of that sorry fruit is its being diuretic, but otherwise it is very harsh and almost bitter, and draws the chewer's mouth almost close. Some pretend this *Kola* agrees exactly with the taste and virtue of the *Indian Betele* or *Anca.*

The *Cola* is the same as in *Guinea*, and so very plentiful, that they export vast quantities to *Loanda* in *Angola*, all in their husk or rind, which preserves it a long time, and is much valued there.

ALLUVIAL SOILS AND THEIR MANAGEMENT.

[THE REASON WHY.]

Alluvial soils are formed by those accumulations of sand, earth and loose stones or gravel brought down by rivers, which, when spread out to any extent, form what is called alluvial land. The word is derived from the Latin verb *alluere*, signifying "to wash upon," as the sea does upon the coasts. The richest alluvial soils are to be found near the junction of large sluggish rivers with the sea, or where they meet in the valleys through which they pass; and the soil is most varied and heterogeneous in the composition of its parts, when these are in minute divisions and intimately blended together. The finest natural soils are thus formed of numberless thin layers of mud by the overflowing of rivers, and left to dry till the next overflowing brings a fresh supply.

Alluvial soils partake of the nature of the earth from which the waters descend, or over which they spread. They may be formed of a clay mud, or of a fine sand or silt, or of a mixture of both, and the layers of these two may alternate according as winds vary and sea currents set in. Clay is more easily disintegrated than any other mineral, and, therefore, always occurs abundantly in every alluvial soil. Marly, and all the newer calcareous rocks, as the oolites and chalk, are easily washed down by the rains and carried off by rivers. Sandstone and trap rock, containing clay and lime; those granites, also, whose felspar contains the alkaline silicates in abundance, are easily decomposed by the rain water and other atmospheric agents, and all their finer ingredients are carried by the streams and rivers to the great deposits near the sea. Alluvial soils thus necessarily consist of minute or impalpable particles of a great variety of minerals; for though the predominating earth may in some be clay, in others lime, and in some sand, yet, derived as they are from all the geological formations which the rivers and its tributaries have traversed, they cannot fail of containing in due proportion every ordinary ingredient.

How may alluvial soils be improved? Alluvial soils are the most fertile of all natural deposits, and require a treatment by which their fertility may be diminished, rather than increased, together with protection from floods, to which they are naturally liable. The treatment of them must also be modified according to their nature. Alluvial soils are of two kinds, one derived from the sediment of fresh, the other of salt water. They will generally bear crop after crop with little or no addition of manure, and with a very slight cultivation. It is in the alluvial soils principally that an accurate analysis is useful, because the proportion of their constituent parts varies to innumerable degrees. It may be laid down as a general rule that the most fertile of these soils are those in which the primitive earths are nearly in equal proportions, silica being the most abundant, with about 10 per cent of organic matter; a greater proportion of the latter would from too loose and spongy a soil to bear good crops of corn, especially of wheat. But 4 per cent of humus, with a good mixture of earths, and some phosphate of lime from the decomposition

of bones and marine shells, produce a very good cheap soil. The rich warp lands along the Humber are artificial alluvial soils, and although they contain but a small proportion of humus, are highly fertile after their first deposition; but it is observed that they gradually become more tenacious and difficult of culture as this humus is carried off by the crops, and that it is soon necessary to add animal and vegetable manures to supply the deficiency.

Lands possessing alluvial soils may be protected from flooding by embanking and draining; and low lands of a sterile nature lying in the neighbourhood of the sea, and of muddy rivers may be rendered more or less fertile by a system of periodical irrigation, called "warping." Warp, or sea ooze, abounds at the mouths of friths, estuaries, or arms of the sea. It is of a most enriching nature, and adds to the staple of the soil. It is used as a top dressing in spring for crops both of grain and grass, more especially for the latter. It is an excellent material for composts, particularly for their soils. It promotes the improvement of garden soils in a manner hardly to be credited; and wheat or oats manured with sea ooze are little subject to rust, mildew, or any other disorder.

It takes some time before any corn will grow on the new warp. At first it looks like barren mud; but it soon dries to a better texture, and ultimately produces very extraordinary crops. If its fertility decrease, and its surface is still below the level of high water, a slight warping, like the inundations of the Nile, immediately restores the fertility. What is curious, is the almost total absence of organic matter in the warp soils, or rather, its intimate combination with the earths, so that it cannot be readily separated from them. It is like neither clay nor sand, but something between the two, soft to the touch, but not hardening into lumps when dry; neither very porous nor very retentive of moisture. The principal earth is silica in a very fine state. It generally contains a portion of calcareous matter, probably from shells. It produces beans, oats, potatoes and wheat in abundance, without any manure. It is admirably adapted to the growth of flax, especially when the warp is of good depth.

The fertility of warped land naturally leads to the conclusion that silica, in a very comminuted state, becomes best adapted for the roots of plants to shoot in, and to supply them regularly with the moisture necessary to their vegetation, that their chief nourishment is derived from the atmosphere, since very little organic matter can be detected in warp, and few mineral substances besides earths. Undertakings of this nature are generally of considerable magnitude, and require large capital. The land to be warped must be banked round against the river. The banks are made of the earth taken on the spot from the land: they must slope 6 feet, that is, 3 feet on each side of the top or crown of the bank, for every foot perpendicular of rise; their top or crown is broader or narrower, according to the impetuosity of the tide and the weight and quantity of water; and it extends from 2 to 12 feet: their height is regulated by the height to which the spring tides flow, so as to exclude or let them in at pleasure. In these banks there are more or fewer openings, according to the size of the ground to be warped, and to the choice of the occupier; but in general they have only two sluices, one called the flood gate, to admit; the other called the clough, to let off the water gently; these are enough for 10 or 15 acres. When the spring tide begins to ebb, the flood gate is opened to admit the tide, the clough having been previously shut by the weight of the water brought up the river by the flow of the tide. As the tide ebbs down the river, the weight or pressure of water being taken from the outside of the clough next the river, the tide water that has been previously admitted by the flood gate opens the clough again, and discharges itself slowly but completely through it. The cloughs are walled on each side, and so constructed as to let the water run off between the ebb of the tide admitted and the flow of the next; and to this point particular attention is paid. The flood gates are placed so high as only to let in the spring tides when opened. They are placed above the level of the common tides.

Willows are also occasionally planted on the fronts of the banks to break the force of the tides and defend the banks by raising the front of them with warp thus collected and accumulated; but these willows must never be planted on the banks, as they would destroy them by giving the winds power to shake them. Warp leaves one-eighth of an inch every tide on an average; and these layers do not mix in an uniform mass, but remain in distinct layers. If only one sluice, then only every other tide can be used, as the water must run perfectly off, that the surface may incrust; and if the canal be not empty, the tide has not the effect.

As a new soil is created by this practice, it is of little consequence what the original nature of the land may be, almost all kinds being improved by it. But at the same time it may be the most beneficial in such light soils as are very open and porous, and such stiff ones as are defective in calcareous matter, and which require substances of this kind to render them less tenacious. Land, when once well warped will continue for a vast length of time in a good state of fertility; but still, it is suggested by some experienced warpers as a better practice, to apply a small portion of warp whenever the land is in a state of fallow, which will be about every five or six years, as by this means the farmer will be more secure of having good crops. The depth to which the lands are covered by the tides must be regulated according to their levels, and the height of the tides in the rivers from which they proceed. It may be admitted to the height of 3 or 4 or more feet; but the deposit of sediment is in some measure proportionate to the height of the water, though the same effects may be obtained from such smaller quantities of water by continuing the process a great number of tides.

Example of Improvement of an Alluvial Soil.—The late Lord Kames, on becoming proprietor of the estate of Blair Drummond, in the county of Perth, began the improvement of a large tract of worthless land. In this case, a good alluvial clay soil had become completely overgrown with moss. Instead, therefore, of attempting to improve the moss surface, it was floated off piece-meal into the neighbouring sea, the supply of water required for this purpose being obtained from an adjacent river. The water being conveyed through the moss in channels, successive layers of peat were dug, thrown in and washed away. The channels were shifted as occasion required, until the whole inert mass was removed. A thin stratum next the clay was then burnt and the ashes used as manure. An immense extent of moss was got rid of, and an extensive tract of country where formerly only a few snipes and muir fowl could find subsistence, was converted into a rich and fertile course of alluvial soil worth from £3 to £5 an acre—15 to 25 dollars. Mr. Ralphe Creyke undertook to reclaim a large area of peat moss in Yorkshire by the system of warping. He resolved to warp from the river Ouse some 1,600 acres. In the following season after the undertaking was commenced 429 out of the 1,600 acres were covered with a deposited soil to the depth of 3 feet. In 1823, this land was sown with oats and grain seeds, and on the fourth year bore an excellent crop of wheat. By this time the other two compartments, respectively consisting of 500 and 671 acres, were completed and in a state of preparation for their first crop of oats, &c. In this case so great was the improvement that the land, which before warping was entirely unproductive, and yielded no rent whatever, in the course of four years produced abundant crops and readily let for 35s. per acre.—*Melbourne Leader.*

CANE AND BEET SUGAR.

BY G. BUCHANAN.

The sugar crop or supply of the world is estimated at five millions of tons. Of this quantity one million tons may be put down to India and China. The cane is grown throughout India, and a small enhancement of value in the export market is soon followed by a large accession of sugar in the bazaar. The export from India is stated in the Statistical Abstract to be 644,531 cwts. But of the real production of the one or the other country very little is known. Omitting them from the calculation, the supply would be four million tons. It consists of cane and beet sugar in nearly equal parts, the figures for the year 1882 being:—

Cane sugar .. ..2,060,565 tons.
Beet sugar... ... ...1,860,994 ,,

This equality of production is, however, not owing to a

like degree of saccharine or sugar bearing capacity in the two plants, but to the more successful extraction of the sugar they contain in the manufacture of the beet than the cane. Were the modes of treatment of equal skill and efficacy in both cases, beet sugar, there cannot be much doubt, would have to take a lower position in the category, notwithstanding the fiscal support accorded to it in the country of its growth. Without the premium on export to stimulate its manufacture, a sustaining power could hardly have been found for the large production in the part retained for home consumption. Beet sugar, until of late years, could not, except in the form of refined sugar, bear comparison with sugar from the cane. The raw beet sugar is from the disagreeable smell and taste of the molasses, unfit for consumption as human food. By skilful treatment, a nearly pure white grainy sugar is now produced without the refiner's aid, but no grocery sugar made of beet can without offence come near the cane muscavado or v.p. caystals. In chemical composition, beet sugar is considered to be identical with cane. Whether it is so in the use also is doubtful. It is suposed to be deficient in sweetening power. And yet raw beet is largely imported for our refiners, and is preferred, perhaps, to the low classes of raw cane for its better preparation, as it is known much less crystallisable sugar can be obtained from beet than from cane of a similar analysis. The consumer may, consequently, be somewhat inconvenienced in pocket, and there being no way of telling one sugar from the other over the shop counter, it would be only fair towards him if a label of distinction were introduced. Analytical figures show that, in moisture and ash, no difference to speak of exists between the kinds of highly refined sugar, whether beet or cane. But they also show the unrefined white beet sugar to be as pure, although to smell and taste it is foul with the "hogo" of the beet that clings to it. If chemistry cannot find out the difference of odour, neither can it of sweetness. This is, perhaps, a matter of taste only, and the common notion that beet is inferior to cane may be justified by fact. It is well known that all the first-class jam makers and manufacturers of British wines will not use sugar made from beet, however beautiful it may look, or however cheap it may be. And it is to the beet in the sugar of the shops, it is said, that is often owing in home-made preserves the disappointment of the cook's expectation of a good jelly. If the difference of sweetness should be 10 per cent less in the beet, it is an indirect taxing of the cane to allow beet sugar to be sold as one and the same thing with cane sugar, and ought to be discontinued.

The crude materials possessed by the sugar market in the cane are acknowledged to be superior to those he finds in the beet, or in any other of the plants from which supplies of sugar are obtained. The advantage claimed for the beet is that the pulp, after exhaustion of the sugary juice, furnishes the cultivator with a valuable food for cattle. And it is this contributive force in stock feeding that to the farmer forms perhaps the chief object in growing the sugar-beet. Unless meat production went along with sugar production, the latter alone would be barely profitable. But as regards the cane, there is—to say nothing of the tops and leaves, which would make good ensilage like the beet tops—a set-off to the spent pulp of the beet in the megass or refuse of the cane after crushing, that is quite equal in value to wood for fuel to the manufacturer. The megass, too, if it could be returned unburnt to the land, would supply the cultivator with the natural fertiliser for his plants. The produce of a crop of sugar-beets in Germany is not more than ten tons of washed and topped roots per acre, whilst in India the native farmers are said to get twelve or thirteen tons of cut canes per acre. In Jamaica the yield is supposed to be from seventeen to twenty tons, and in Demerara twenty-five to thirty tons per acre. In France, where the beet is cultivated less for the sugar it affords, and more for the advantage of the pulp to the farmer, much larger crops are grown than in Germany, from twenty to thirty tons per acre being a common yield. But the bigger beets have inferior saccharine matter, and the deficiency of richness is not compensated for by the greater quantity produced, as the adverse chemical salts and other bodies inimical to sugar crystallisation increase also, not only in proportion to the sugar, but even to the gross weight. In quality, the juice of the cane is both purer and richer than the juice of beets. Weight for weight, the former has almost double the amount of sugar that the latter possesses; and taken when the cane is fully matured, the juice is said to be almost a pure syrup, and more free from contamination with uncrystallisable forms of sugar than beet juice. By analysis, the ripe cane is shown to contain from 13 to 22 per cent, with a mean of 18 per cent of sugar. The beet contains from 5 to 10 and 11 per cent of sugar, with a mean of 7½ per cent. In Germany, where the roots are taxed on the weight without reference to excess in the relative amount of sugar in them, the proportion has, with high cultivation, risen to 13·75, and even a percentage of 18 appears to have been reached; but this may be looked upon as a maximum of the laboratory difficult of attainment, and in practice not more than 13 per cent of sugar should be reckoned upon as the average in good years. The cane is also a more favourable crop to cultivate than the beet, giving less trouble, requiring less labour, and suffering less from vicissitudes of the weather. The cane roots send up a succession of young shoots, or rattoons as they are called, for three and four or more years; whilst for the beet, an annual tilling and sowing of the land is necessary; and the rattoons, taking into account the shorter time of growth, may be considered to yield as abundantly as the plant canes. The great drawback in cane cultivation is that seed time and harvest fall together, causing the pressure of work to be doubly heavy in the season.

Where the cane is seen to be apparently inferior to the beet is in the course of extracting the juice. The sugar-beet contains from 94 to 96 per cent of juice, and all of it, with the exceptiou of 5 or 6 per cent can be extracted. From the cane, on the other hand, only 60 per cent is obtained of the 88 to 90 per cent of juice that it contains. The new and enlarged mills, with rollers of greater length and diameter, will procure a yield of from 65 to 70 per cent, but the common run of mills do not get more than 45 to 50 per cent of the weight of the cane in juice. The resistance to a fuller surrender of the juice is sought to be overcome by using more powerful machinery on the same principle, and as much as 80 per cent of juice is said to have been expressed in experimental trials. But that this extra yield should be secured in the crushing of a whole crop of canes is scarcely to be expected. And beyond a certain point the excessive power employed would not be paid for by the increased quantity of juice, or the quality of what is got. The juice drawn from the lighter and less complete crushing of the cane is known, by the experience of the old cattle mills, to be the best. That which comes away, under more forcible pressure, may have a greater density, but it is the objectionable salts, albumen, and fragmentary fibre of the cane which increase in it, and not the sugar. Besides pressure is practically inoperative to squeeze out of the crushed body of the cane the juice that it holds hygroscopically or retains by absorption. And it is only the wealthy owners of estates who can bear the cost of these big mills. No inconsiderable portion of the sugar must, therefore, continue to be lost, and the full profit of the manufacture fail to be got, unless a change can be made in the mode of treatment, and some improved method, such as would extract the saccharine matter from the cane as effectually as is done in the beet, be adopted. In the beet-sugar manufacture, which began upon the plan used with the cane, the old mode of extracting the juice by pressure has in Germany, nearly, if not altogether, given way to the diffusion process, with its auxiliary methods for saving the sugar in the molassess. And in France, where roller and hydraulic presses are still generally employed for the convenience of the farmers, who require to have the compressed pulp returned to them, and get back from the best mills as much as 20 per cent in weight of the beet roots supplied, that is from 5 to 6 per cent of solid residue, holding 14 to 15 per cent of juice diluted with 18 per cent of water, many of the large factories have begun to substitute diffusion for pressure. That the diffusion process can be applied successfully to the cane has been also demonstrated. By its use at the Aska works in Ganjam, India, 87½ per cent of the 90 per cent of juice in the cane has been abstracted, and, according to a published return, an average yield of 83½ per cent was obtained from

the crops worked off in the three years ending in 1870. In Guadeloupe the almost absolute exhaustion of the cane juice was effected by it; and in Louisiana, by the competitive trials of pressure and diffusion made in 1874, a surplus was shown in favour of diffusion over mill of from 40 to 43 per cent, obtained at a cost of but 1·30$ more per 1,000 lb. of sugar and molasses. But whether diffusion is in ordinary practice the process most suited for economic use in cane-sugar making, and would be as fully applicable to the cane as other processes, remains still to be determined. In growth and structure the cane is dissimilar to the beet. The one has a long slender stalk above ground, formed of strong paralled fibres, and divided by knots every few inches apart. The other has a short stem distended under ground, made of vascular pulp, and with a long tap root. And as they differ in substance, the tendency of the sugar and water to pass through the walls of the closed cell until equalised by transference, which is the condition of diffusion, will vary in some degree. But the position of the sugar cells in the cane, the largest number being found about the softer parts in the middle, should make it easier to displace the sugar by diffusion than to expel it by pressure through the rind. Defective, however, as the ordinary machinery for extracting the cane juice confessedly is, this is not the only or chief difficulty in the way of an extended sugar production. A greater obstacle is perhaps the want of time and labour in harvest. The canes, of which the gross quantity is enormous when compared in bulk with other crops, have to be cut, carried, and converted into sugar within the short space of three or four months. In manufacturing beet sugar, on the contary, the period of working can be extended over a longer time, and the roots kept for later use, or till germination begins in spring, by storing them in pits. And it were a thing much to be desired, if the means of relief could likewise be found for the cane-sugar maker.

Great interest is shown in discussions upon the beet-sugar bounties, which are an evil, regarded from the refiners' point of view, that is not unmixed with good to the people of this country, but indifference appears to be profound on the subject of cane sugar. And yet it is indisputable that we, with our tropical possessions, are as distinctly a cane-growing people, as on the Continent they are beet growers. We are concerned not so much with how they manage things in France and Germany, as with what we can do to double and treble the produce of our own sugar-fields. The consumption of sugar per head of the population of these islands has more than doubled in the last quarter of a century. And were it not for the largely-increased supply of beet, the price also would have been very appreciably affected. The relief of their wants recived from the cane by those who take sugar has been small in comparison to that given by the beet. On a decennial estimate, the contributes only an additional amount of 277,958 tons, against an increased yearly quantity of 987,994 tons furnished by the beet. The relative figures for the two periods are—cane sugar, 1872, 1,782,607 tons; 1882, 2,060,565 tons; beet sugar, 1872. 873,000 tons; 1882, 1,860,994 tons. The cane is thus seen to be no longer the most important factor in the sugar market; and the superiority of the beet in this respect is further shown by the crop of the following year, 1883, with its enormous yield of 2,146,534 tons of sugar. No wonder, then, if exaggerated ideas of its potentiality in the future should be conceived, and the beet be looked upon as king, going on ruling, and to rule the markets. The legitimate claim, however, of the cane to the first place in the market of this country will very generally be admitted. But its restoration can only be brought about by producing good and cheap sugar more abundantly. And how is this to be done? It is an important question in endeavouring to deal with which it may be allowable to make one or two suggestions. To say we are not justified in trying experiments, and must let improvement wait upon success, is to wait behind. As a good field for action, therefore, take Jamaica. It is easy of access, and its natural advantages of soil, water, and climate enable it to compete with other sugar-growing countries. The island has, unfortunately, suffered a long period of decadency, since the time of emancipation, and of the Act of 1846, equalising the duties on free and slave-labour sugar. But the official returns show that there was no decrease in the value of the staple and other products during the ten years ending in 1880. And if the year 1881 was a bad year, from blight and other causes, the year 1882 was a "bumper," and the exports of sugar, regard being had to the increased size of the hogshead, were the largest of any year since 1847—signs that present a good augury for the future. There is evidence, too, that the black and coloured population, already numbering more than half a million, are becoming sensible of new wants, and feeling a desire even for luxuries. The continual extension of provision grounds must cease to be profitable, or to provide a lazy subsistence, and the Negro, if he would have the means for an enlarged expenditure, will be compelled to prosecute the cultivation of the old commercial products of the country that are in repute abroad. Labourers for sugar estates are said to be scarce in some districts, but are commonly to be hired at from 5s. 3d. to 8s. 9d. per week of five days, the people not caring, or being pushed by want, to turn out on Saturday. And hundreds of men have left the island for Colon, engaged to work on the Panama Canal for wages of ten cents per hour; a strong proof that employment is not plentiful, and of a willingness to seek it under the attraction of good pay. Much land is lying waste and unproductive in both public and private ownership. The area under cultivation, including pasture, is 554,162 acres, out of which the average acreage under cane for five years, ending 1881, was only 43,999 acres. Of that vacant cultivable land a part might be very well applied to the growth of canes, and by the introduction of the East India system of farming, turned to good account. In India the ryot, as the peasant farmer is called, has usually in his holding a small patch of sugar cane growing with his other crops. The produce he makes into goor, or raw concrete sugar, and sells to the refiner, who turns it into clean white sugar for consumption. And experience shows that the ryot, giving his immediate care and attention to the work, and aided by wife and children, does better and more economically than a factory or sugar works, dependent on hired labour, and having the supervision of an extended area, can manage to do. The ryot has his plough, bullocks, rude crushing mill, and boiling pans, and when in want of money can, on the security of his interest in the land, obtain advances from the native banker. The adoption in Jamaica of this system is, however, not advisable in its entirety, but only so much of its as relates to the culture of the land, which, by the consension of opinion in India, is best left in native hands. The negro is not so inferior in capacity to the ryot that he could not, if put in the way and helped in the beginning, farm his small holding as efficiently, and secure in a market for his canes, do it successfully. The small agriculturists in Jamaica, making their couple of casks of sugar yearly, of whom there were 5,615 in 1871, though reduced in number to 4,700 in 1880, witness to this. But their example in being sugar makers is to be followed rather in the avoidance. With the cropping of the canes the proper work of the agriculturist ceases. The extraction of the sugar in them requires skill of another kind, and separate machinery; a fact that seems naturally to indicate a division of labour between the planter and the sugar maker, as there is between the paddy grower and the rice miller. Supposing, then, an estate, with 300 acres of suitable land, to be laid out in plots of convenient size for cultivation by a family, say 5, 10, or 15 acres, and let to the occupants at a fair rent on a fixed settlement, either perpetual or subject to revision after a period of years, there would be on the average 30 families, and counting the usual five in a family, a population of 150 attached to the land; a number that should afford more than a sufficiency of labour for its proper cultivation, since from two to three labourers are enough to plant from 8 to 10 acres; and if it were made a firm stipulation of the tenancy that three-fourths of the holding should be kept in cane-bearing, the sugar-works would only have to provide a supply of labour, required concurrently with the machinery, to convert the canes into concrete sugar for refining. In these small holdings there might, at first, be little room for any but the commonest implements of husbandry, yet opportunity would come to introduce carrying and other labour-saving machinery in aid of the manual labour of the occupiers. Formerly land, mill, and people made one machine, but the people have since be-

come a part detached; and if a well-ordered land and sugar company could be framed on these or similar lines, the moneyed man might reasonably hope to find profit in aiding the readjustment of the mechanism for its new work. The numerous little sugar estates that are in Jamaica would naturally group around and co-operate with diffusion works placed conveniently near them. On some of these estates cattle mills are still in use; on others, where water or steam is the power employed, the ordinary roller presses are wanting in capacity. For these small properties to incur the expense of new or enlarged machinery, in order to obtain better results in sugar making would be economically less to their advantage than to spend the money in improved and useful agricultural instruments. As to raise the percentage of sugar in the juice would be more for the common good than if they were to increase the percentage of juice expressed. A successful grower of canes might, by selling to the adjoining diffusion works, lay his account to reap all the farming profit, and by taking a prospective interest in the sugar made, participate in the profit of manufacture also.

As regards keeping the canes for later use, when cropped, there are two things to be noted; the great liability of the juice, as an aqueous solution of sugar, to ferment on exposure to the air, and the influence of heat to turn it sour. The tendency of all vegetables upon reaching maturity is to fade and spoil. Sound ripe canes, however, deteriorate but little if the skin is unbroken and the sugar cells are not ruptured. The juice is produced separately in each joint, and the plant ripens from the bottom upwards. Cut canes have been known to keep for days without harm, and even with positive advantage the ripening of the top joints continuing to form sugar. Fermentation is said only to take place in a solution of sugar and water when sufficiently dilute, with less than four parts water to one part sugar it takes place imperfectly, if at all. As, therefore, the proportion of 18 sugar to 90 juice is just 1 to 4, the natural drying up of the cut canes should help to preserve them. In these circumstances it might be possible, if there was available space, to stack and keep the upper part of the stalk, whilst using the lower part that has ripened, and thus to lengthen out the time for working in the sugar-house. The means employed to lower the temperature and prevent the heating of hay in the rick, would probably answer with the cane, and by facilitating evaporation accelerate the reduction of the water in the juice to a safe point. Were the experiment successful, and the practice of storing canes to come into use, sugar works would be able to maintain a permanent gang of skilled workmen, and to carry on operations with a smaller outlay for machinery. But the drier the canes became, the less amenable they would be to pressure, and for the liberation of the juice it might be needful to have recourse to a solvent like the water of diffusion or maceration.

These processes, maceration and diffusion are the opposites of one another. Diffusion is applied to, and acts upon, the close cell of the plant; maceration on the open cell. And the advantage is with diffusion, which, applied to the beet, has surpassed maceration in success. By crushing the canes, the cell walls are burst open, and with the admission of air to the juice, fermentation begins. The juice gets also mixed with bits of broken fibre, mucilage, and other parts of the substance of the substance of the cane, which are washed out with it in the act of maceration. Impurities are left behind, or not meddled with in the course of diffusion, as in slicing the canes a certain number only of the cells are cut open. The cells appear to act as clarifiers, the sugar passing through the cell wall, to change places with the water outside, whilst the albumen remains inert. The diffusion process, as improved by Julius Robert, dates from 1864-5, and was first applied to the cane at the Aska works, in the year 1866. From the reports of good success in the use of it by this company, its introduction into Louisiana followed in 1873. Twenty years before, in 1845, in Guadelope, attention had been directed to a plan of putting sliced canes, in baskets, into copper vessels with water. But nowhere in the British possessions, excepting at Aska, does there appear to have been any endeavour made to prove the capabilities of the system for working up our cane crops. In Louisiana an apparatus used before for beet was brought over from Europe and set up; on trial, however, it was found to be unfitted for manipulating sugar-cane, and two new and complete machines were constructed for use on separate plantations. Upon one of them, where the common kettles or open pans, used for making brown sugar were employed, the diffusion juice failed to granulate so readily as the juice from the mill. On the other plantation, where an exact test was made between the mill, an ordinary three-roller mill, and diffusion, a vacuum pan being in use, the result demonstrated a considerable gain by the diffusion process. Disagreements, however, arose between the parties concerned in the affair, which prevented further experiments from taking place. The next year the two diffusion machines were removed and set up on another plantation, and canes were purchased for working. But the season was most unfavourable, the canes did not ripen well, the transport arrangements were bad, there was no pecuniary benefit, and thus the enterprise failed. The apparatus was worked two or three years after this by the people who bought it, but only on a small scale, and finally they took it down and re-erected the mill. With more judicious management it is very possible the process might have been made a success, as the gain in saccharine matter was great. At Aska, also, the working of the diffusion process was said not to have been continued, a sure sign it was no success. But so far is this from being the fact, that the process is still in successful practice, and has been yearly for seventeen years. At the works they now cut up during the season 1,000 tons of canes a week, and are so satisfied with the results, that they have ordered out a complete apparatus of the newest construction.

In Germany, 12½ cwt. of sugar beets were formerly assessed to make 1 cwt. of crystallised or grain sugar, equal to a yield of 8 per cent. But now, owing to improved cultivation and manufacuture, it is believed that in good years, 1 cwt. of sugar is obtained from 11 cwt. of roots, being a return of 9 per cent. In France, not more than 5½ per cent of grain sugar is made from beets containing 10 per cent of saccharine matter. About 2 per cent is procured in the form of molasses, and of what remains, rather more than ·3 per cent is given up in the pulp to the farmers. The losses in manufacture will account for the rest. In Demerara, 12 cwt. of canes, with an assumed extraction of 66½ per cent of juice, make 1 per cent of grain sugar, equal to a yield of 8⅓ per cent. In Jamaica, the exports, on an average of the five years before mentioned, with the sugar made by the small settlers, which is mostly consumed on the island, show a production of less than one ton of sugar per acre, or a yield of 5 per cent. But on many of the estates, it may be noted, a large proportion of rum is made, Jamaica rum fetching more money than the rum of other places. In Martinique, 13 cwt. of canes, with an extraction of 65 per cent of juice, are taken to make 1 cwt. of sugar, giving a return of 7·62 per cent. The yield, however, at one of the usines, as the works are called, with an extraction of 77·94 per cent, is stated to have been 8·91 per cent of grain sugar. In other words, 11¼ cwt. of canes made 1 cwt. of sugar, a result as good as it is perhaps exceptional to have accomplished. The theoretic out-turn gives, nevertheless, a greater yield. For instance, taking the sugar in the canes to be 18 per cent and the juice 90 per cent of their weight, the amount of sugar in the juice is found to be 20 per cent. Then $11\frac{1}{4} \times \frac{20}{100} = 2\frac{1}{2}$ cwt., of which an extraction of 77·94 per cent is 1¾ cwt. And this, allowing for the change of a fourth of the sugar into molasses, shows a loss of one-third of a cwt. in every cwt. manufactured. No account is made of the juice abandoned in the megass from inability to get it, or the loss would appear considerably more. But take the exponent 1 to 13 as a better index of the proportionate production of sugar to cane in good mills. Then $13 \times \frac{20}{100}$ as before = 2·60 cwt., the full contents. And if 85 per cent of juice be extracted, we get 2·21 cwt. of sugar and molasses. A result that is tantamount to a loss by the ordinary mode of manufacture of cwt. per cwt. In such a case it becomes a pertinent question, how to avoid this loss. In practice there must of course be some waste, and unripe and damaged canes will also cause a destruction of sugar. Yet as it is possible to get the sugar in the beet with a discount of little more than 1 per cent, it cannot be thought a thing impossible to obtain it from the cane without the forfeiture of as much almost as is made. And it is evident

that, if the pressing mill has failed to do it, the diffusion process gives promise of greater success. In the Louisiana trials diffusion used only 9⅜ cwt. of canes, when the mill took 13¾ cwt. to make 1 cwt. sugar and molasses, equal to a yield of 10·37 and 7·27 per cent respectively. At Aska works the yield is much larger, amounting to from 13 to 14·8 per cent, and more than has been obtained by the mill anywhere. It has been objected to the diffusion process that an excess of molasses is produced, and the first run of diffusion in Louisiana showed an excess of 6·79 per cent, the proportion being—

Diffusion ... ... 50·43 sugar, 49·56 molasses.
Mill ... ... 57·22 „ 42·77 „

But in the second run of diffusion there was no excess, the proportion being—

58·48 sugar, 41·51 molasses,
or 1·26 per cent or less than the mill.

It will be noticed how large was the quantity of molasses made both by the mill and diffusion, caused probably by the weak character of the cane juice, which does not always ripen successfully in that region. Whether there would be a continued diminution of the amount, the nearer diffusion was brought to perfection in working, it is hard to tell. Since the failure of the process in Louisiana, the attention of the planters has been given to the better grinding of the canes, by adding to the 3-roller mills in use a 2-roller mill of greater strength and capacity. But seeing what has been done at Aska by diffusion, it may be fairly concluded that the ratio would be decreased. Less than one-third of the product manufactured there is molasses, the proportion on an average of the three years before cited being—

Sugar, 68·06; molasses, 31·93,

and hitherto they have been working the process in wooden vessels made in the country.

To recapitulate, the comparative production may be approximately shown thus:—

				Sugar.	Molasses.	Pulp and Begass.	Loss.	Total.
Diffusion ...	Germany	Beet, 11 cwt.	make 1 cwt. sugar	9·09	2·00	0·70	1·21	13
Mill ...	France	„ 18 „	1 „	5·50	2·00	1·32	1·18	10
„ ...	Demerara	Cane, 12 „	1 „	8·33	3·00	4·66	2·01	18
„ ...	Martinique	„ 13 „	1 „	7·69	2·75	5·00	2·56	18
„ ...	Full extraction ...	„ 13 „	1¾ „	13·46	2·54	1·00	1·00	18
Diffusion ...	Aska	„ 10½ „	1 „	9·45	4·45	1·30	2·80	18

This Table illustrates the superior skill and enterprise displayed by the beet sugar manufacturers, and their success in dealing with materials of an inferior natural character, in the competition with cane sugar. It does not, however, give a full statement of the case between the beet and the cane, nor does it show how utterly the cane sugar producers have failed to turn to profit the advantage afforded them in the relative yield of the two plants. If the growth of an acre of canes gives a crop of 20 tons, it would, at the rate of 1 to 13, afford a yield of 1½ tons of sugar, or by a full extraction of the juice, 2¾ tons per acre, and the produce of an acre of beets of the richer sort being only half that quantity, or 10 tons, the yield of beet sugar cannot be put higher than 18 cwt., or at the very most, one ton per acre. Now, comparing the great productive capacity of the cane with the largest return obtainable by skilful management from the beet, it would not be too much to say that it will be a reproach if a continuance of the present state of things should be allowed. The sugar planter, not generally well-found in means, may certainly see it to his advantage, when harvesting his large crops of cane, to make a small extraction of the juice, acknowledging to himself that, as was said of old, "He is a fool who knows not how much more the half is than the whole." But if the planter is content to take what he can and not what he may, and expedite his work, the impolicy of this waste, and the need of a reform in the practice, will be recognised by the merchant and the refiner. The coming-in of beet sugar upon us like a flood is not a desirable thing to contemplate by any one interested in the prosperity of cane sugar making, and it is only by aiding the development of this great source of wealth which the country now holds in neglected possession that the invasion can be met and stayed. In any remedial measures to be taken, the first thing is, as directed in an analogous case of some note, to "catch the hare," that is, to obtain from the cane a saccharine fluid not only as pure and rich as possible, but in as large a quantity as may be shown to be practicable. The further operations of concentrating the juice and refining the sugar are, it will be admitted, of secondary importance. It is proved the sugar is there, in the cane, and is procurable in a greatly increased amount. The call, then, for improvements in the manner of manufacture will not, it may be hoped, when sustained by the Society, be uttered in vain.

Worthy, however, as the cane must be acknowledged to be of receiving our exclusive attention, it is yet fortunate that there is at hand in the beet an ancillary sugar bearer to which, when stinted in the supply of cane, we can turn for the relief of our wants. And deserving the sugar beet (it is a mangel wurzel) is to be called "scarcity root," considering how large a quota it furnishes to meet the requirements of our greatly increased consumption, the needs of which would, with cane alone, have caused ere now a sugar famine. According to the Board of Trade returns, the imports of sugar into this country amounted in the year 1882 to 1,130,267 tons, of which more than a third, or 395,915 tons were beet sugar. But the unrestrained admission of this portion of the supply is objected to by the home trade, and strenuous endeavour has been made to restrict the importation of beet by the imposition of a countervailing duty of £2 per ton, which, as was shown before the Select Committee on sugar, would suffice to equalise the foreign bounties given to the exporters. That the claim has not been conceded is scarcely surprising; the wonder is that it was ever made. The rules of free trade have never been shown to be so considerate of the growers of corn or sugar, as to give reason to suppose they would be indulgent to the second-hand traders in the same products, the millers and melters. And an artificial bar of this kind put up in the way of beet sugar would be surmounted by the manufacturers improving their machinery, and adopting new processes to extract all the sugar possible from the saccharine of the root. The diminution in value by the tax would be compensated by the augmentation in quantity of the sugar; when the controversy would begin again, and a cry be raised to have the barrier made higher. A surer way to stop the influx of the objectionable commodity would be to lower permanently the price. The present low quotation prevailing in the sugar market will, doubtless, lessen for a time the production of beet on the Continent, but so soon as the demand overtakes the supply, and prices rise, the cultivation will be followed up and extended. One-half the time and pains that have been taken in an unavailing opposition to the foreign bounties on beet, would, if given to the introduction of improvements in cane-sugar making, have furthered the object of the planters and refiners more effectually. And that without injuring the consumer, who, when provided with better and cheaper cane sugar, could have no cause to complain of the displacement of beet sugar from the market. But it almost seems as if our people had lost a great deal of their relish for the sweet cane, and had more liking for the unsavoury beet. For instead of applying skill and money to the development of cane sugar works in the Indies, the habitat of the plant, the manufacture of sugar from beetroot is to be commenced in this country. A former attempt to make sugar in Suffolk

failed, and it may be doubted if the present trial will be more successful in meeting foreign competition. As although home-grown beet will have a considerable advantage over that from abroad in the saving of freight, &c., the humidity of our climate is almost as great a natural disadvantage. In Germany the wet bulb thermometer shows 2 to 3 degrees more cold than here, indicating the air to be less damp, which is conducive to more richness of sugar in the root. But the depreciation in value from over-production is a greater discouragement to beet sugar, for if it was unable, as supposed, to bear the burden of a tax of £2, how can it endure the fall, as reported, of £4 in the market. This decline must be a very serious thing for the growers, and yet sugar can scarcely be said to be too low in price, compared with other articles of food, if the equivalents of their value for food are considered. The natural effect of low prices is to stimulate consumption, and seeing how extensively sugar is employed in the diet of the people, it is for the public benefit that it should be cheap. If the beet-sugar manufacturers have no margin left for working on with profit, and cannot eke out the failing price with a fuller quantity of sugar from the root; the cane-sugar makers are not in the same evil plight. Their situation compares favourably with that of their rivals, and they may look forward with hope and conviction that cane-sugar planting can be made to pay well, although the day of such high dividends as 30 per cent on the capital employed be past and gone.

UNRESERVED SALES OF TEA.

The rapidly increasing state of the Indian tea trade, and the enormous number of samples to taste in each day's sale, point to a much-needed reformation in the mode of selling. As at present constituted, the sale-room offers are accepted or refused too often according to the fancy of the individual broker who occupies the rostrum, and between "box customs" and the means employed after auction to get prices up to sellers' valuations much valuable time is lost, and the patience of the trade sorely tried. There appears to be only one way out of the difficulty, and that is to sell Indian teas "without reserve." Brokers' valuations may be very interesting to themselves and their clients but buyers cannot be guided by them. The valuations of the sellers are not certain, and perhaps it may be said, are very unreliable. The true worth of the teas on sale day we most unhesitatingly affirm to be the auction offers when sold without reserve. Brokers should know this full well, for it is the exception to get advances on the sale-room offers and more frequently money is lost by refusing them. Withdrawn lots are a decided nuisance to dealers as well as a great trouble to brokers for neither the one nor the other in busy times can devote attention to them, and the result is they are neglected till reprinted, and 99 times out of 100 "the second time of asking" brings out less money. There are too many conflicting interests in the London auction room to allow a tea to be thrown away under market value; notwithstanding the fact that some irresponsible valuer may consider the lot a cheap one. It has lately become the expressed opinion of the trade that the Indian tea sales should, like the kindred trade of China teas, be without reserve; and it must become the common rule sooner or later. Any novice attending the auctions can see the difference between a reserve and an unreserved sale, the one dragging along and the other full of life. As all the tea imported has to be sold sooner or later, it is simply a question to be settled by the importer and the broker when it will be best to offer it, and once they have decided on a certain day, let the teas be disposed of in the public sale-room. We should then hear less about losses for one thing, and the daily work would be quickly got through. Nervous importers will not readily agree to sell without reserve, but those who care to take good counsel will reap the greater advantage. The London wholesale dealers are quite alive to the fact when they wish to clear off remnants of their stock by auction, their invariable practice being to offer such lots without reserve, as they know such a condition of sale ensures the attention of buyers, while without it they would be neglected.—*Home and Colonial Mail.*

THE JOKAI (ASSAM) TEA COMPANY, LIMITED.

CROPS OF HALF-A-MILLION LB. OF TEA COSTING 10½D. PER LB. TO PRODUCE.—DIVIDENDS 6 TO 8 PER CENT.

The above company having made arrangements for the acquisition of several neighbouring estates upon favourable terms announces an increase in its capital. A new issue is made of £60,000, of which £11,000 in £10 shares has been offered for public subscription. The following is from the prospectus:—This company was formed in Calcutta in 1873 for the purpose of acquiring and working the Jokai and other estates, and the head office was transferred to London in 1882.

The dividend for the past three years has averaged six per cent., and with the view to lower the cost of production through economies in administration and European management, negotiations have been completed for amalgamating the Muttuck tea plantations, which are contiguous to, and in some instances interlace with, the Jokai division of the company, and contain an area of 435 acres under plant, from which 180,160 lb. of tea were gathered last year, and showed a profit of about seven per cent on the value taken over by this company.

The award on which the basis of the amalgamation has been fixed was given by Mr. J. J. J. Keswick, President of the Bengal Chamber of Commerce, who, as senior resident partner in the firm of Messrs. Jardine, Skinner & Co.'s of Calcutta, has had large experience in the valuation and financial management of Indian tea estates. He determined the price to be paid to the Muttuck Tea Company, Limited, for their estates and assets to be £19,000.

Favourable arrangements have also been made to purchase or lease several smaller estates in the neighbourhood, the management of which will not involve any increase in the present staff of the Company. The Board intends to take advantage of any further opportunities for acquiring other estates in the immediate vicinity, provided such amalgamation will help still further to reduce the cost of production.

In order to provide for the purchase of the above estates, the capital of the Company has been increased to £120,000, of which £30,000 was raised, and a further issue of £30,000 is now made, comprising £19,000 allotted to the shareholders of the Muttuck Tea Company, and the balance, £11,000, is offered for public subscription. The remaining 6,000 shares are reserved for future issue upon the purchase of additional estates, and for other purposes of the company, in terms of the Articles of Association.

The amalgamated estates already purchased, and those agreed to be purchased, will comprise more than 8,500 acres, of which 4,581 acres are held under fee simple tenure, and the remainder on very satisfactory leases, direct from Government. They are all within from three to nine miles of Dibrugarh, the chief town in Upper Assam.

The outturn of tea this season is estimated at 581,600lb. (458,000lbs from the company's own estates, and 123,600lb. from gardens held under lease) which it is expected will be produced at a cost of 10½d. per pound laid down in London. The outturn to end of August has been telegraphed, viz., 357,900 lb. or more than three-fifths of the total season's estimate, thus giving every reasonable hope that the full crop, as mentioned above, will be realized, and possibly exceeded.

The new shareholders will have the benefit of the present season's crop.

The gross amount realised for the produce of 1882 and 1883 was £28,495, showing an average of 12·62d. per pound. Taking the cost at say 10½d. per pound laid down in London, there remains a margin of, say, 2d. per pound, which, on the outturn of 581,600 lb. estimated for 1884, would show a surplus of £4,850, or equal to a dividend of over 8 per cent. upon a called-up capital of £60,000. The portion of the current season's crop so far sold—viz., 61,621 lb.—has averaged gross 1s. 2·15d., or 1½d per pound in excess of the figures on which the revenue calculations have been based.

The company's mark has for years maintained a good position in Mincing Lane, the crop having realised 1s 2¾d in 1881, 1s 0¼d in 1882, and 1s 1d in 1883.

A return, issued by the Secretary Indian Tea Districts Association, shows that the position of this company compares favourably with fourteen other first-class dividend-paying tea companies in Assam; the average cost per acre being £49 10s., and the cost of production 11¼d per lb of tea.

The capital cost per acre of the estates of this company on the same basis is £40, and the cost of production per pound is estimated at 10½d for 1884 season.

The following agreements for sale and purchase of properties have been entered into between the Jokai (Assam) Tea Company, Limited, and the liquidators of the Muttuck Tea Company, Limited, dated March 11th, 1884. Correspondence between John Berry White and Messrs. Finlay, Muir, & Co., regarding purchase of Sherwood estate: contract, dated February 9th, 1884, between John Berry White and Richard Rowe, as to lease of Kalijan estate; contract, pated February 20th, 1881, between John Berry White an Khetsee Doss, regarding leaseof Baugpara and Poma gardens; an agreement, to act. as produce brokers of the company, has also been made between Messrs. Lloyd, Matheson, & Co., and Mr. Alex. Lawrie, dated June 9th, 1884.—*H. and C. Mail.*

INDIAN TEA IN AUSTRALIA.—The following occurs in a report of the meeting of the British Indian Tea Company:—

"A shareholder asked whether they had tried to dispose of their tea in the Australian market, which he understood was a very good one for China teas. The Chairman replied that the Indian form of tea packages were unsuitable to the Australian market. They had tried the experiment of putting their tea up in half-chests similar to those used by the Chinese, but even then they would not sell, and he believed they had lost about £500 by their experiment. He thought that whatever Indian tea was sold in the Australian market would be more as a sort of curiosity than as a staple aricle of c mmerce.—*Indian Tea Gazette.*"

As most of the India tea purchased in Australia is used for blending, we do not think the nature of the chests has had so much to do with the disappointment as is supposed. The question is one of price, and pure, good Indian tea cannot be sold at the rates for which the Australians have been accustomed to purchase inferior China stuff.

THE BRAZIL COFFEE CROP: LARGE PROPORTION OF LIGHT COFFEE.—The *Correio Paulistano* remarks as below on the prospects of the forthcoming crop:—After the different opinions concerning the present crop, based on *bull* or *bear* ideas, it is possible today to guarantee that the crop unquestionably is smaller than that of 1883, and the quality will be, moreover, inferior. On the plantations, where *washed* is prepared, this is evident, for the proportion of coffee that floats in the tanks is much greater than the proportion of other years. Some months ago, observers, seeing the trees heavily laden with fruit, concluded that the crop of 1884 would, at least, equal that of 1883. Today, this may confidently be denied on account of the light (*chocho*) beans that are appearing. Never before did this phenomenon so clearly appear. One-third of the berries are *chocho* or imperfect; so that the gathered crop must suffer a considerable reduction when prepared, 30 per cent at least. The crop will therefore, unquestionably, be inferior to that of 1883 both in quantity and quality. As to that of 1885, if the weather favours it, if no further frosts occur, nor sensible decrease of temperature it will probably be one-half of the present crop. While the effects of the frost were not so great, as at first was stated, nevertheless they much (*muito*) affected the life of the trees and their sap for blossoming. Adding to the above the fact that very little of the old crop remains in store, and that considerable new coffee has been marketed, the planter should be forewarned against speculations. The position of the article cannot in any manner be bad, production is reduced on a sensible scale, now as well as for the future, therefore it cannot escape the fatal laws of supply and demand. Do not let planters hurry forward their crops; the storage of their coffees in their stores will produce more than sufficient to meet the losses caused by delaying their shipments.

MR. ROBERT CROSS ON RED BARK CINCHONAS AND ON INDIARUBBERS.

The letter from Mr. Cross, the well-known plant-collector, which appears below will be read with interest by planters. It will be observed, that, as regards indiarubber trees, Mr. Cross is strong on their being allowed to reach a fairly mature age before being operated on. In that case, he states, they will bear milking for a score of years. It is evident that much of our disappointment with rubber in Ceylon has been due to the too early tapping of the trees.

Passing on to the cinchonas, Mr. Cross broaches the opinion that there must be something wrong with the bark from Ceylon to account for the unremunerative prices recently obtained. We believe there is nothing wrong but the over-abundant supply and, perhaps, the large proportion of twig bark sent into the market. In an early stage of the enterprize, the late Mr. John Eliot Howard characterized the cultivated barks from India and Ceylon as largely superior to the barks gathered in the forests of South America, and not long ago Dr. Trimen showed how the proportion of quinine in red bark increased with age and altitude. We have recognized varieties of *succirubras* in Ceylon, although not by any means so marked as in the case of *officinalis*, but the amount of quinine and of alkaloids generally has been referred not to differences of type so much as to age, altitude at which the plants were grown, and to the fact of the bark being allowed full time to renew after the stripping or shaving process. Scientific men have not recognized the essential difference in red barks on which Mr. Cross insists, and, while the analyses to which he refers us and our readers show excellent results, Mr. Cross, unfortunately, does not enable us to institute comparisons between the inferior and the superior varieties, nor does he help planters to the characteristics by which the superior red bark which he claims to have introduced, can be distinguished from the inferior which, so strangely, Mr. Clements Markham and others persisted in foisting on India and Ceylon. Cinchona planters would be too glad to confine cultivation to superior kinds alone, if only Mr. Cross would describe the points of difference in foliage, blossom, fruit, bark and habit of growth, between his superior varieties and the ordinary plants available. At present, we suppose, in view of the glutted market and correspondingly low prices, the tendency is either to abandon cinchona culture altogether or to confine attention to the most robust and best quality hybrids and the ledgerianas. Attention to best quality red barks might be still continued, if Mr. Cross would only be good enough to give full and detailed descriptions by which such best quality could be identified, or better still were Mr. Cross to arrange for a good supply of either seeds or plants for sale here of his superior red bark trees.

We think it probable that Dr. Trimen, who regards the Pata de Gallinazo of Mr. Cross as a figment, will have something to say on the present allegation that most planters in India and Ceylon have been wasting money on inferior red barks when the true and superior plant was, according to Mr. Cross, available.

MR. ROBERT CROSS, THE PLANT COLLECTOR, ON CINCHONAS AND INDIARUBBERS.

(*To the Editor, "Tropical Agriculturist."*)

Glasgow, 9th Sept. 1884.

SIR,—A little over two years ago, after arrival on the Nilgiris with a collection of *cinchona* plants for which I was sent by the India Office to South America, I pointed out the mistake which had been made in planting in some of the plantations there a poor kind of *cinchona*, the Huanuco bark of Peru, for the *Cinchona succirubra* or true "red bark" of Chimborazo, plants of which were dug up by myself in their native habitat and brought to India 20 years previously.

At the time of introduction of the *cinchonas* into India, it so happened that the Huanuco bark and the "red bark" reached India about the same time, were propagated in the same hothouse, during which operation they seem to have got mixed together, and in this way the "red bark" plants were lost sight of. There is, of course, often a considerable resemblance between young plants of the Huanuco and "red bark" when growing in a fertile soil and especially when forced in a hothouse.

In India as in South America, two distinct varieties of "red bark" are recognized. One of these has smooth foliage, while the leaves of the other are hairy underneath. These are respectively termed by South American collectors the *pata* and *teja* or "tile" bark.

Before leaving India I collected samples of these together with some "Crown" for purposes of comparison. The objects in view were:—

1st.—To compare the yield of the *pata* with the *teja*.

2nd.—To place both these sorts against "Crown."

3rd.—To observe the increase of alkaloids which takes place as the bark grows older.

Just lately these samples have been analysed, for which I am entirely indebted to the obliging kindness of David Howard, Esq., F.C.S. Most of the samples, as will be seen, were of renewed bark, the aim being to secure bark of each sort of the same age. However, it will be understood that among trees of similar size, one tree from any particular circumstance may develop thicker bark than another in the same space of time. I beg to direct attention to the surprising purity of the contents of the bark and the small proportion of the inferior alkaloids contained therein when compared with the yield of quinine.

I will further express my opinion that when really good species are cultivated an ample yield of the best alkaloids will follow. On the other hand, when a planter is fighting with mixed-up seed of inferior varieties no superior system of cultivation will avail.

It is out of the question that any sort of bark should be sold at such low prices as we have seen recorded for several parcels from Ceylon sold at Mincing Lane some time ago. There must be something immensely wrong to induce this state of things, though, as I am unacquainted with the climatic conditions and other circumstances of Ceylon, I will not express an opinion on the subject. At the same time it occurs to me that one or two very simple avoidable circumstances are at the bottom of the whole affair.

I am glad to learn from some newspaper reports that the indiarubber trees which we originally collected on the Isthmus of Panama and in Brazil are thriving in Ceylon. The trees of all three species, the *Castilloa*, Pará, and Ceará, should be allowed to attain a good size before being operated on. They will then bear to be tapped or milked every day for nine months of the year. If the wood is not much injured in this operation (the *Castilloa* is most sensitive), they will bear working for 20 or 30 years. The widespread mode of making cuts or incisions or by slicing off a portion of bark may be tried on the Ceará tree. The tapping process which is performed by making two cuts like a V at the base of which a small cup is luted on to the tree by means of clay is largely practised in Brazil. The method often adopted in collecting *Castilloa* milk in Central America is by making a perpendicular channel in the bark of the trunk with lesser channels leading into it. These we

have fully explained and illustrated in reports on the subject.

I shall feel obliged if you can find room for these notes in your valuable paper. Annexed is the analysis of the *cinchona* samples alluded to.—I am, sir, your obedient servant, ROBERT CROSS.

CACAO, PEPPER, LIBERIAN COFFEE, AND CARDAMOMS GROWN NEAR THE SEA-COAST, CEYLON.

Mr. T. S. Dobree has been giving us a favourable account of the enterprize in new products in the Udagama district (Galle) which he so pluckily and laboriously initiated and fairly started. Mr. Dobree laid the colony under an obligation by almost leading the way, among colonists, in the lowcountry cultivation of pepper and cardamoms, besides cacao, tea and Liberian coffee. Of the last-mentioned product 200 acres were under cultivation, and on 80 acres of these, a very good crop is now ripening, the leaf-disease apparently giving less trouble the older the coffee grows, but "black bug" this season has perhaps checked the fungus! Some 50 acres of the "coffee" are to give way to tea, but the rest of the 'Liberian' will it is hoped continue to crop and pay the proprietors, more especially if the price improves. We found our Philadelphian "Friend Morris" very eager to get 'Ceylon Liberian' unhusked—as he gets the African kind,—the cherries being allowed to wither into ripeness and perhaps to fall before being gathered and shipped. After being "hulled" in America, a very high price is got for this fine-flavoured coffee, and the husks are sold for more than the freight and incidental expenses of the whole! Mr. Dobree doubts however if this plan could be followed in our wetter and more uncertain climate where a heavy shower would dash half-ripened berries to the ground, and to dry the Liberian cherry in store would ensure an unpleasant flavour the beans.—The Cardamom crop on Udagama is most satisfactory and yet such trouble as there was in getting this product underway! Out of of the first thousand bulbs from Matale, perhaps 100 were got to start. Now, all is plain sailing, only experience shows that to guard against the effects of a dry season, planting on the edge of ravines or otherwise in moist situations should be preferred. As elsewhere, the difficulty is to say when cropping is to stop even after estimates are got in during the present season.—Tea is to do well at Udagama and on Monrovia (Capt. Bayley's property) and if the railway is sent on to Bentota and Galle, most certainly a great deal of produce will come from the south to Colombo, while the railway would entirely shut up Galle as a port of shipment.—Pepper is one of Mr. Dobree's most interesting new products, and further experience would lead him to amend in some respects the hints he gave us not long ago as to its cultivation. He would have cotton trees planted out in good 2-feet holes two years at least, to be ready for supports, before taking the pepper vines from the nurseries.—Cacao grows well in the sheltered hollows in which it has been planted in Udagama, having no enemy but *white ants*; but they do prove a real and terrible foe both to the cacao and cotton trees, while never touching the Liberian Coffee. "Supplying" the cacao walks, has to be constantly carried on to counterbalance the loss by white ants.—Altogether though the operations on the Udagama properties in a multiplicity of products have passed from the stage of preliminary experiment into one of almost assured success; the great advantage is economy in working, the labour being chiefly Tamil and the cost of keeping the place as free of weeds as a conservatory never exceeding 75 cents an acre. For such contract work as cutting roads holes, drains, &c. Sinhalese are employed; but they cannot be depended to work for more than two days at a time. The work of supervising, cultivating, cropping and curing the variety of products is of course far more responsible than the old easy routine of the coffee-planter; but it is also far more interesting, and we are glad to learn that the health of Superintendents and labourers in the Udagama district has been uniformly good.

TEA AT KALUTARA.—The growth of tea in this district (from sea-level to 300 feet a titude) is such as to occasion alarm among old planters as to whether the plant is not to become uncontrollable and carry all before it like lantana! All the way down the coast towards Galle and Matara there is plenty of room for tea, and the Sinhalese are beginning to cultivate, more especially on little plots of land which they buy adjoining the larger plantations. The object here would seem to be to force the big proprietors to buy them out by-and-bye; but tea is scarcely so available for the depredation of thieves as coffee, cacao, or even cinchona. Tea leaf plucked haphazard at night would not be worth much, nor could it be sold like parchment coffee or bark. The railway still carries very little of the supplies to or the produce from this district. Even tea is sent by boat, while all the rice supplies so travel. Water carriage is of course very cheap, but for tea, speed and safety from moisture ought to count. Here again, the aid of an experienced planting or mercantile member on a Railway Board of Management would be invaluable, to point out how new business could be secured.

Correspondence.

To the Editor of the "Ceylon Observer."

MASKELIYA: A PERFECT CLIMATE FOR TEA.

Upper Maskeliya, 20th September 1883.

DEAR SIR,—In the *Observer* of the 15th instant, I see Maskeliya for July is the second wettest district in Ceylon. Now, to show you how unfair it is of the P. W. D. only publishing the rainfall from one part of the district, I herewith enclose what was measured, most carefully, by me on this estate during the past year. I think you will say that it is a perfect climate for tea.

September 1883	rain	fell	on 7	days	total 4·64 in.
October	,,	,,	20	,,	8·70
November	,,	,,	25	,,	11·74
December	,,	,,	14	,,	5·77
January 1884	,,	,,	10	,,	4·09
February	,,	,,	7	,,	2·28
March	,,	,,	18	,,	9·64
April	,,	,,	15	,,	9·47
May	,,	,,	18	,,	8·58
June	,,	,,	17	,,	6·65
July	,,	,,	17	,,	3·51
August	,,	,,	21	,,	5·31
Total days rain fell ... 189					Total...80·38 in.

Since writing the above, I have read the letter in yesterday's paper from a correspondent in Maskeliya. He will find in the above an answer to his enquiry.

W. D. B. B.

[It is refreshing in this year of drought to get a complaint of one's district being represented as too wet. We have no doubt that Maskeliya will take very high rank as a tea district.—ED.]

SMITH'S PATENT FIBRE MACHINES.

Galle, 23rd Sept. 1884.

DEAR SIR,—I find on referring to the *Observer* of the 10th inst. the following para having reference to "Smith's Patent Fibre Machine":—"Ten of Death & Elwood's machines have been supplied to one district in Southern India, and some doubts that were recently cast on the success of a machine tried in the south of Ceylon have been scattered by the chief operator confessing he had made several blunders in his way of working, his jet of water having far too little fall, while the raw material was fed in above rather than below the guard."

Mr. S. E. B. Curtis of Baddegama is the gentleman who has given the machine a fair trial in the south of the island, and, as that para can only refer to him, I, as agent in Ceylon for Smith's Patent Fibre Machine, asked him what it referred to. In reply, he tells me he made no such improbable confession. Will you, therefore, kindly contradict the statement? Mr. Curtis has nothing but praise for the way the machine does its cleaning and says the principle is excellent.—I am, dear sir, yours faithfully,

T. S. CLARK.

[It is not the principle of the machine or the quality of the fibre it turns out, but its capability of clearing a paying quantity of fibre per diem, which is in question. We understood that Mr. Campbell it was who tried and reported unfavourably of the capability of the machine, but he afterwards confessed he was mistaken. When we have local evidence of its doing a paying amount of work as well as good work, we shall be delighted to publish more facts.—ED.]

NEW PRODUCTS, LEAF-DISEASE, &c.—No. VI.

DEAR SIR,—From the leaf of a brinjal (egg-apple) plant, the *melongena* of botanists, an insect was taken out of a swarm of them on the under-part of the leaf which presented patches of a sooty appearance. The insect was less than one-sixteenth of an inch in length, pale greenish, more inclined to brown colour: under the microscope it appeared to be a veritable and beautiful beetle; the wings were transparent and reticulated with the nerves and blood-vessels, although the latter appeared to be devoid of colouring matter. The whole surface of the body of the insect was hairy, rather spinous-looking under the glass. The insects appeared to be devouring the leaf, as its destruction seemed to be rapid. The sooty appearance above alluded to, I believe, is the larva of the insect. [Its excrement more likely?—ED.]

Several of the branches of the brinjal plant had already been eaten before I took notice of it. I then got a quantity of cold ash thrown over the plant, and on the third day I was glad to observe the plant presenting a more healthy appearance and the soot completely vanished. I have no doubt in my mind that cold ash has a beneficial effect on the plant in preventing the ravages committed by leaf-insects, besides being a good fertilizer.* For large plantations it would be necessary to use a duster, and I would suggest the construction of one on a large scale, of an instrument upon the principle of a syringe, but with the mouth or the nozzle expanded and perforated. The cylinder of the syringe being filled with fine cold ash could be squirted by the propulsion or handle of the instrument, but the cylinder must be lightly filled with ash: in this manner many trees may be operated upon in a few minutes. The employment of labour for a few hours to operate on the plants and on both sides of the leaves will be amply compensated by the saving of so many trees from destruction, and would be worth trial. The instrument may be made to rest on a stand which can be moved on wheels as per enclosed sketch, which will give an idea of the instrument.†

Whilst on the subject of the brinjal, it may be useful to describe the uses of it, and the mode of preparing the varieties of curries which are made from brinjal and are daily used by the people. There are varieties of the brinjal, the long-shaped which are about 12 or sometimes 15 inches in length; there are white and purple of this kind. Again, the real egg-apple is globular, sometimes the size of an ordinary custard apple; the taste is similar in all, and they can all be made into some kind of curries. There are white and purple of this kind also.

Esculent property of the brinjal.—There is scarcely any fruit equal to brinjal in its nourishing qualities. It is easily cultivated, and every variety of it abounds in properties necessary to sustain life, although an excessive indulgence in it is said to produce irritation of the blood, and, consequently, skin diseases. The natives say that it is *kerendé* or blood irritating; however that may be, the brinjal is a very nourishing food in form of salad and curries. In the curried state it is that the brinjal is most used, and descriptions of the mode and varieties of curries which are made of it may be useful.

As a salad, the brinjal is cut into round slices and boiled; then the necessary condiments viz., vinegar, salt and pepper are added and served at table.

Cutlet is made by dividing the fruit into two, boiling them carefully, scooping out the fleshy and seed parts of it, whilst the skin is preserved unbroken. The fleshy parts are squeezed well and some

* It may yet be found that cold ash is the best specific against the ravages of the leaf insects. [The coffee leaf-disease is a fungus.—ED.]

† In applying sulphur and lime on a large scale to coffee, all machines were ultimately discarded in favour of coolies hands defended by coir gloves or mittens.—ED.

minecmeat is added, a little salt also; then the compound is laid in the skin, which is hollowed out, then the thing is baked to a brown colour, a little lime juice is added if necessary or according to taste and served at table, and is eaten with potatoes or bread.

Vinegar curry is made by slitting the brinjal into four, which is boiled in watery coconut milk, to which the usual condiments are a little saffron, a few green chillies slit lengthways, some salt, and over the whole is poured a little vinegar; then boiled and before taking it down a little thick milk is added; this is generally used with rice.

Fried and Curried.—This is by far the nicest of the dishes: the brinjal is slit into four or eight and fried in ghee or good expressed coconut oil; then the curry is made as above but without vinegar, the fried brinjals are put in and boiled in the curry to some dryness; this is also always eaten with rice.

Curry-stuff curry is made by cutting the brinjal into small bits and boiled with a little ground coriander, dry chillies and saffron, a few prawns or a bit of dry fish or Maldive fish must be added; then boiled in watery coconut milk to evaporation, and before the curry is wholly done a little thick coconut milk is added and allowed to evaporate; then taken down; this with the addition of a little olive oil with rice makes a strengthening and substantial meal.

Simple curry is made by slitting the brinjal and boiling in coconut milk, to which are added the usual condiments mentioned above. When made watery and a little more chilly and some vinegar are added, the curry is called *pulleeyanam*, a great favorite with the poor natives as it combines strength with taste to the food and is economical in its preparation.

Brinjal chutney or *pachee* is an excellent appetizer, and is made by roasting brinjal, the fleshy part taken out and squeezed, then some vinegar, mustard, a little ground chillies are added and served: this is a nice concomitant to the ordinary dishes of rice and curry.

Minced Curry or Melloon (*Sinhalese*), *Chundal* (*Tamil*).—This is made by cutting the brinjal into very small pieces and boiled to evaporation; then a little salt a few bits of green chillies and some quantity of scraped coconut are added and boiled again, when the remaining water becomes dried leaving a dry composition, which is eaten with rice.

There is a species of brinjal which grows wild: they are almost shrubs; the fruits are very small and round but bitter and full of seed; the poorer people collect them for curries. One variety of the brinjal grows to large trees with thick spreading branches; the fruits are globular but larger than the above, are full of seed and are greedily eaten by cattle.—Yours truly,

SILEX.

TEA AND JÁT.

DEAR SIR,—I have to thank you for publishing my two letters on this subject, written solely with the object of eliciting information. The passing allusion in the first letter to the unfortunate spec I made in plants last year was wholly unpremeditated; and these form so small a fraction of my planted area, that, beyond being a "caution" to myself and others, the point is of the smallest importance. I have, however, got some other stuff in, here and there, for which I am solely to blame; and, as—to judge from all I am told—many others are committing the same mistake, I deem the subject worth ventilating. Your readers have benefited by the two editorials, both interesting, and the last one containing all that can be desired on the subject of the three leading játs, though I must be excused for chronic blindness to any allusions to "ját" in the former.

I had no idea who "Cranston" was; and I now learn, for the first time, that "an article" must necessarily be "editorial."

I am prone to linguistic and clerical laziness, and often omit words I think redundant at the moment, but you, sir, at all events, have not mistaken my meaning viz.: "Which statement is true?" On looking again, I find I had omitted "the little crooked thing that asks questions." The answer you have given to this question is that the statement that *China tea is best* is the prejudiced vapour of a retail vendor of the celestial kind, by the sale of which he had probably shrewdly calculated he could make most profit, that Colonel Money is too enamoured of the pure indigenous Indian plant and that Baildoo is the true oracle for Ceylon planters.

But what I want more light thrown upon is the "hybrid." Here is one word applied to "a hundred varieties," and I submit that, so far as I can learn, no sufficiently authoritative article, letter, essay or dissertation or guide, has been published in any available form. I want to know what is practised in Ceylon. Not long ago I passed through a well-known estate and counted (or could see) thousands of spikey-leaved Chinamen in full bearing. Again, only the other day I was in a neighbour's nursery in which were several beds filled with well-grown plants from the seed from a crack Ceylon estate which seed it is even now difficult to obtain. There was no mistaking the excellent quality of the larger portion of the plants, but neither was it possible for even a half-trained eye to overlook the (to me) surprisingly large percentage of inferior things, proving a certain admixture of Chinese with the Indians which must be growing on the said crack estate. Now, whence had these poor plants come? Unquestionably from the imported Indian seed, and, when that estate was planted, the very caution which I am now endeavouring to inculcate had not been practised. *All* the plants which grew up in the nursery from the imported seed were put out, and I suspect that, with certain exceptions, the same thing is being done this year by Ceylon planters inexperienced in tea, many of whom, probably, my experience as here set forth will serve to warn. V. S.

TEA PREPARATION: HEATING AND DRYING MACHINERY.

23rd Sept. 1884.

DEAR SIR,—The discussion on improved methods of a drying-house, resulting from the appearance of a paper on that subject by Mr. William Cameron, which apparently terminated last March, was most valuable and interesting. I have been digesting what I then read, and I would like to state a difficulty or two which troubles me somewhat. Clerihew's system had a twofold object, viz., first, to *draw down* a current of *hot* air through heaped wet coffee, and, secondly, to *draw down* a current of *cold* air to keep fresh and sweet coffee which was already dry but which had a tendency towards deliquescence in wet weather. For this purpose a two storied building was required, each story performing its own function. The top story was rendered air-tight and a passage was left below the reepered flooring by nailing on cloth rendered air-tight by starch and lime. This was the cold air room, and the action of the fans pulled the air through the heaped coffee, thus saving the expensive and troublesome necessity so well-known to all coffee-planters of turning the coffee with shovels. But in a wet climate and during a heavy crop there was often a terrible time of anxiety to the planter resulting from an accumulation of wet-washed coffee in the cisterns. In "bumper" days it was not altogether an unknown thing to have the coffee *sprouting* before it got a chance to dry. Now comes

in the *hot air* room. I need not describe the "battery" of pipes and the furnace playing on same, nor need I describe the merrily spinning fans at the other end. We had the fans at work, as I have shown in the cold air room. Now, light the furnace and go in when the temperature is 160° Fahr. You will have a practical idea how far Clerihew is superior to Cameron. Squat on your haunches, then stand up straight. The heat is greater the higher you rise. Walk straight up to the hole where the flue enters the room and try and look down. You will get a blast more effective than Mark Twain's pipe. Stoop under the opening, and the temperature is not very severe. Well, suppose we agree to put the opening towards the fans at the top. We will then assist nature to do what she is bound to do by herself; *i. e.*, to let the hot air rise and escape at the top. That would result, as "J. B." so well expresses it "in the current of the hot air from the hottest part of the flue taking the easiest course to the fan." And where is the material to be dried? According to Clerihew heaped largely on the floor; according to cacao-planters, spread very thinly on the floor, each cacao bean having a certain space to itself; according to Cameron, hung all over the shop on trays "moveable or otherwise." I am prepared to maintain most decidedly, that, if Cameron raised his temperature, say to 160°, his material would be most irregularly dried, whether he got rid of the air at the top or bottom. If he stuck to the suction at the top, the layer at the foot would be injured by want of heat, and the highest layer would also be injured by extreme heat. When I speak of raising the temperature to 160°, I mean raising the temperature of a given point in the room, say five feet from the floor at the "fan" end of the room. This ought to give a fair idea of average heat employed in the room. Now, I do not consider that material can be fairly dried by a system of trays. You must have separate floors with their own special openings to the flues, and the fans then will draw the fresh hot dry air across the spread-out material and out below the matting.

Increase your fan-power, and the drying power will be increased at less cost of fuel.

I see "W. F. L." says much the same thing, but is silent on the point of the necessity of shelves or trays. No doubt it seems to be a great economy to choke your room full of trays, and save area by so doing; but the results will be so irregular and unsatisfactory, that it would be necessary to shift the trays by rotation to get an even sample. Cameron will find it very easy to go "with the stream"; but the difficulty is *not* to let the hot air pass up by natural pressure through the wet material, but to subject this material to a *dry-hot* current of air *over* the surface and thence out underneath. That is the only way to effect what "W. F. L." calls "exhausting the room every two minutes." It would be utterly futile to attempt this in any other way. If we wanted hot air for a propagating house, or for the purposes of heating a room to make it bearable to an audience in a northern clime, then Cameron's "drier" would be called a "heater," and thus cease to be a misnomer. But we have a material *to be dried*. It is laid down wet, and we want to take it up dry. Where does the moisture go to? It must be carried off sharp, because some materials would very speedily [*sic*: absorb it?—ED.] such as cacao for example. But, if the fresh dry-hot air gets encouragement to follow its natural bent, the moist air is handicapped, and damage as well as waste of fuel occurs. It seems to me that Mr. Cameron's ideas of a drier would be more useful in a hot-house where *steamy heat* as a stimulant to vegetation is needed rather than in the curing establishment of a cacao-planter.

ABERDONENSIS.

PAPAW JUICE.

London, 26th Sept. 1884.

DEAR SIR,—I see that you refer to me in regard to papaw juice both in this paper and in the *Tropical Agriculturist*. I have made a study of this drug, and I am aware it is coming into use under the form of papaïne, and I hope shortly to be able to send you a pamphlet, the result of some good work done in Germany, but the papaïne that has been used there surpasses any that we have hitherto known of for strength, and it does not change by being left in an ordinary corked bottle. I would therefore strongly recommend that no expense be incurred until these facts are known.

In drugs of the strength of papaïne, it is very important to work with standard strengths. We have at the present time three different strengths of papaïne, and all three differ from one another in appearance and colour.—Yours truly,

THOS. CHRISTY, F. L. S.

TEA PREPARING MACHINERY.

Bangalore, 29th Sept. 1884.

DEAR SIR,—In the *Tropical Agriculturist* of the 1st January 1884, page 474, reference is made to a simple and inexpensive tea roller. Such a machine, it is there stated, has been invented by Mr. Kerr and will soon be offered for sale. I shall be much obliged if you will kindly give me information on the following points either by letter or through your journal:—

1st.—Is the machine now for sale? and its price?

2nd.—If so, has it been found by experience fully to answer as an efficient tea roller?

3rd.—Is there any other hand tea roller procurable? and, if so, please give any information you may have regarding its qualities, price and the maker's address.—Yours faithfully, JAMES ROSS.

[This enquiry will show the need for the patentees or agents of new tea or other agricultural machinery advertising the same in the *Tropical Agriculturist*, which is becoming the recognized representative journal of planters in so many places outside of Ceylon. Mr. Kerr will no doubt communicate at once with Mr. Ross, in reference to the questions asked about his tea-roller.—ED]

TRANSMISSION OF CEYLON TEA SEED TO THE WEST INDIES.

DEAR SIR,—I have been asked by a friend to get a small quantity of Ceylon tea seed for a West Indian sugar planter. The seed would have to be sent to England and from thence to its final destination. Would you or any experienced tea planter inform me as to the best way for packing tea seed, to be kept out of ground nearly, if not quite, two months after picking? It would be very disappointing to all concerned if the tea seed failed to germinate on arrival after being carefully gathered and selected, and would most likely stop all chance of large orders later on.

When there is no longer any demand for our seed in the immediate neighbourhood, we may more than make up for it by orders from the West Indies, as the sugar planters there will, it is more than likely, be one and all looking out for *new products* to take the place of sugar. In order that the seed which I hope to send may not damage the fame of Ceylon tea in any way, I shall feel obliged if anyone more experienced in such matters will help me with their advice.—Yours faithfully, ENQUIRER.

MARAGOGIPE COFFEE.

Henaratgoda, 2nd October 1884.

SIR,—It appears that the shell of the Maragogipe coffee bean is of a more delicate nature than the other varieties of coffee. The seeds require careful

treatment in preparing the nursery. The soil should be well pulverized about one or one and half foot deep. The top of the nursery about one and half inch should be filled with a mixture of two parts soil and one part powdered charcoal. Cover the seeds lightly about half-inch shade and water twice a day morning and evening all other treatments same as for Arabian coffee, if the soil is poor, mix well-decayed cow-dung manure (one-third manure to two-thirds soil). Seeds will germinate in five to seven weeks. Germination completes in twelve weeks.

J. P. WILLIAM & BROS.

[With the above came sketches showing the comparative sizes of the Arabian and Maragogipe coffees. The latter is twice the size of the former. But our correspondents do not seem to have seen the unfavourable notice of the big coffee which we quoted from the Java papers.—ED.]

THE NEED FOR ADVERTISING COCA SEED IN THE *TROPICAL AGRICULTURIST*.

Harchateh Estate, via Bodenackanore,
2nd October 1884.

DEAR SIR,—Could you kindly let me know where I could get coca seed from, and at what price?—I am, dear sir, yours faithfully,

GEO. WM. CLARIDGE.

TEA PLUCKING.

Colombo, 17th October 1884.

DEAR SIRS,—I have seen it frequently stated by correspondents in your columns, that, in taking large yields of leaf from our tea bushes, we are exhausting them, and in the course of a few years they will not only cease to yield but finally die from the effects.

I think you also hold the opinion that we should give our bushes that rest which the climate does not afford, but what advantage we can gain by "kicking against the pricks" is a puzzle to me.

Seeing how small a percentage of the leaf European planters pluck compared with the Chinese, and that nipping off the young shoots as fast as they grow cannot, to my mind, have a tithe of the effect of pruning and topping, the idea appears to me to be opposed to commonsense and experience.

Will Dr. Trimen or any of your scientific readers give us their opinion, as to whether there is either rhyme or reason in the assertion? and whether any benefit will arise from trying to counteract the forcing nature of our climate.

Can our plucking young shoots, and thus checking the surface growth, be more injurious than coppicing or pruning?

We know very well that in the case of bushes and trees, to which these processes are applicable, the effect is not destructive. Take cinnamon amongst tropical evergreen plants as an example of the duration of one deprived twice a year, not only of a large portion of its leaves, but of its limbs also, without apparently shortening its life.

Do we kill hedges of various kinds by clipping them or grass by mowing it! I am told by my barber, who is an experienced French coiffeur, and should know, that the oftener I get my hair clipped the stronger it will grow. Yet I am asked to believe that if the same process is applied to my tea plants I will kill them.—Yours truly,

T. P.

["That rest which the climate does not afford"; but certainly the climate does afford a comparative rest at intervals, and, if pruning be properly done, must there not be an abstention from plucking for an appreciable time afterwards? The comparison between cinnamon or cinchona coppiced twice a year and a tea plant plucked every month of the year, as "T. P." would have it, seems rather far-fetched.—ED.]

MINERALS IN CEYLON.

Upcountry, 20th Oct. 1884.

DEAR SIR,—Can you oblige me by telling me if the enclosed is a metal of any value? It looks to me like tin.—Yours &c.,

J. A. R.

[The piece of ore sent to us, mainly ironstone, was surrounded with a bright-looking metal, very like tin in appearance, but, on being tested, it proved, as we suspected, to be iron pyrites with a good deal of sulphur.—ED.]

JACKSON'S TEA SIFTER.

Upper Abbotsford, Lindula, 24th Oct. 1884.

DEAR SIR,—I am most happy to be able to give the following testimony in favour of Jackson's Sifter. I altered the wire mesh from 10, 8, 6, to 12, 10, 8, and last Monday, on using it for the first time after the alteration, it sorted 4,000 lb. of tea in 5½ hours, or at the rate of nearly 800 lb. per hour. It was altogether most perfect work.—Yours faithfully,

A. M. FERGUSON, JR.

"TEA-LEAF" AS A PRODUCT FOR NATIVE PILFERERS: "PEPPERCORN" AND EDITOR HAPPILY CAUGHT!

DEAR SIR,—Residing as I do in the immediate vicinity of a native village, the remarks of Mr. Peppercorn (p. 401) and the suggestions in your editorial (p. 405) fill me with alarm.

The patient plundered planter has at length fallen across a product which, owing to the comparative difficulty of turning the raw material into a marketable article, is fairly secure from depredation. Too many of us know to our cost how frequently the crop on our outlying fields of coffee turns out terribly short of our very reasonable expectations, while our friend Appuhami, who owns a small wattie adjoining, is agreeably surprised at having underestimated the produce of his few lanky, semi-abandoned trees. Why, in the name of all that is conservative, should we, now that coffee has failed us, go deliberately out of our way to enable our friend to carry on the same old game with our leaves (and at the same time without our leaves) as he did with our berries? I fail entirely to see the force of Mr. Peppercorn's argument. He starts by asserting that "he will ever find a stretch of tea a barren field for his absorbing enterprize," and forthwith proceeds to demonstrate how "he" may render it a fruitful one. Ideals have usually a pleasing appearance; and I grant the various little patches of tea, each of which contributes its quota towards swelling the stream that flows into the central factory (owned, ideally, by Mr. Peppercorn, who is not at the same time an estate proprietor), make up a sufficiently attractive one; but I doubt muchly whether that gentleman were he both factory-baas and proprietor of adjacent tea bushes, would perceive the humour of giving ten cents for a pound made up of two thirds of his own and one-third of Appuhami's tea? Let the native stick to coffee, cinchona, cardamoms or cacao, which afford *ample* space for the development of his enterprize, and of which the last is, according to the Director of the Botanical Gardens, peculiarly suited for village cultivation, a suitability which has presented itself so vividly to the minds of certain parties that they, to quote the same authority, "are even *purchasing* seed;" but leave, oh! leave us our tea. As Mr. Peppercorn, with charming naïveté, remarks (the italics are mine): "The villagers would *very soon* learn what to pluck, and, as the green leaf can be carried a considerable distance without harm, *all anxiety about curing would cease*, and the ready cash system at the factory would suit the buyer *as well as the seller*." The last statement I venture to doubt.

EX NIHILO NIHIL FIT.

WHEN AND HOW TO SHAVE RED BARK TREES.

SIR,—Will one or more of your experienced readers help me to decide the following question, viz. :— *When* and *how* to shave a large acreage of four-year old succirubras? In the *Tropical Agriculturist* for May 1882, Mr. C. H. Symons is reported to assert that "harvesting bark to the best advantage to the grower cannot be done haphazard at any time of the year." It is only natural to suppose such an axiom to be true; and since that time, doubtless, experience has accumulated. The Uva and Kandy seasons differ for coffee, and probably also for cinchona? My field of *cinchona succirubra* is in Ambagamuwa. Is the sap now, in October and November, *up* or *down*? Is this the right time of the year to shave to the best advantage? or does a risk exist of the tree being injured.

INEXPERIENCED PLANTER.

[Possibly the reply from a merchant may be "Wait till the market turns," or "Shave away when you see that a big price is available"; but for the planting answer to his question, our correspondent should consult the "Cinchona Planters' Manual." Usually the wet season is considered to be the best time for stripping or shaving as affording the best chance of renewal.—ED.]

INDIA:—CROP AND WEATHER REPORT.

FOR THE WEEK ENDING THE 15TH OCTOBER 1884.

GENERAL REMARKS.—There was rain in all districts of Madras during the week, and some improvement is noticed in those parts of the Presidency where prospects have hitherto been unsatisfactory. Rain has fallen generally all over the province of Mysore, and the condition of the crops has been improved. In Coorg prospects continue favourable. Rain is still urgently wanted in several parts of the Deccan and Southern Mahratta country, and crops are reported to be withering in the eastern talukas of Poona and parts of Belgaum. Fodder is also scarce in several talukas of Dharwar and Belgaum; elsewhere in the presidency prospects are generally good.

In Bengal the aman crop, which has been improved by the late rain, is expected to yield well if there is heavy rain shortly. In Assam prospects are generally good.

The last report of the Meteorological Department, dated 16th instant, states that rain has fallen over the whole of the Madras Presidency, with the exception of the Kurnool, Bellary and Cuddapah districts, and that slight showers are reported from Mercara and from two districts in British Burma; elsewhere there has been no rain.

Harvesting continues in Madras, and ploughing and sowing for the rabi are in progress in Bombay, Bengal, North-Western Provinces, and Oudh, Punjab and the Central Provinces. The kharif is being harvested in Bombay and the Punjab.

The public health is generally good. Prices are fluctuating in Bengal and the Punjab; elsewhere they are generally stationary.

MADRAS.—General prospects fair, except in Bellary, Anantapur, and parts of Madura and Coimbatore. There have been some improvements in these tracts also during the week.—*Pioneer.*

A NEW APPLICATION OF INDIARUBBER.—Under this heading *Nature* of Oct. 2nd gives a translation of an article in *La Nature*, which, after referring to the many uses to which indiarubber may be put in its various forms, describes an ingenious invention, by which all sorts of household objects can be made to keep their position on a table when the latter is tilted to an angle of from 45 to 50 or even 60 degrees. This is done by furnishing the various articles with a band of red indiarubber fixed in a groove in the bottom rim, which band by its adhesiveness to hard objects permits of the articles furnished with it being placed at the angles mentioned. For cups, plates, bottles, &c., on ships in rough weather the invention will prove extremely useful.

TEA IN AMBAGAMUWA, Oct. 16th.—The enormous yield of Mariawatte is certainly very encouraging, but it is not the only estate that is doing well. I hear that Galbodde has picked quite 900 lb. per acre from its best fields, and should pass the 1,000 lb. before the year is out. Seeing the fine prices which the produce of this estate usually realizes, the return to the proprietors at the end of the year should be splendid. If I mistake not, some of the best fields of tea on this estate are on old coffee land.—Local "Times."

TEA AND TEA DRINKING.—By Arthur Reade. (Sampson Low.) Mr. Arthur Reade made a hit by his little book on *Study and Stimulants*, which appealed to a wide audience, and was, moreover, largely compiled from autobiographical letters. The present volume—in some sense its complement—will scarcely prove such a success. The subject was capable of much more interesting treatment. We have often wished to know what Dr. Johnson paid for his tea, and how much one of his cups held. A book on tea omitting any allusion to the outbreak of the American War of Independence, and a chapter on the foes of tea without reference to Cobbett, show that Mr. Reade has left much for his successor.—*Academy.*

SOUTH WYNAAD NOTES.—Vythery, Oct. 8th—The oldest cinchonas I have seen here, are some about fifteen years old, originally planted among coffee, which last had quite "gone out." It is not, however necessary to go back so far, for there are dozens of estates in Wynaad where the cinchona, though only planted five years ago, and kept carefully lopped, has seriously damaged the coffee. One often hears in Wynaad an expression of regret at having planted up cinchona in a good field of coffee. The objection to associating the two trees is, that they are both surface-feeders, and cinchona being the stronger, deprives coffee of its nourishment. The best shade trees, such as jack, are selected, because they send their roots down to a great depth, and do not interfere with the coffee.—*Madras Mail.*

THE FRENCH VINTAGE.—A recent notice in a home paper gives a cheerful estimate of the prospects of the vines :—

The Vine interest in France is looking up. From many distant quarters come reports that the plants appear richer and greener this year than they have ever been since the phylloxera got the upper hand, and hopes are somewhat prematurely expressed that the pest is wearing itself out. But the truth seems to be that, in some districts at least, the downpour of two winters ago partially drowned out the insect: the only effectual mode of destroying which is inundating the vineyards wherever land and water lend themselves to the operation. The early part of the year, when the vine blossoms, was generally unfavourable to unsheltered localities. Cold winds by day, and colder nights, were adverse to the knitting of the fruit, and the flowers "ran"—*coulaient*, as the vine-grower says. The consequence is that the bunches carry quantities of little abortive grapelets which must harm the wine. There is, too, a very general complaint of anthracnosis, mildew, and the oïdium which first covers the grape with a fungus, then blacken, and bursts it open, and finally rots it away. Frequent sulphuring of the young shoots, the leaves, the buds, and the grapes by means of a special bellows, is the only remedy for this; but the labour costs money, and it is not always properly practised, nor, it must be confessed, always quite successful. Plants which still struggle against the phylloxera are yet so weakened by its attacks, that their fruit is often a total prey to these other diseases, especially in the damper climates. We are promised from Rheims a grand champagne vintage this year as to quality; the vines are looking splendid. As to quantity it will be but moderate, owing to "coulage" in the spring and the present excessive heats. On the Loire there are no complaints save where heavy hail-storms have been at work. In the extreme south there is a great outcry about the terrific heats; the grapes in some places roasting instead of ripening. In the Cognac districts the remnant of the vines will give what is rurally known as a "jealous" vintage—very good here, bad there, and middling farther on. The native vines grafted on American stocks are now beginning to tell wherever they have been planted and are the healthiest of all."—*Pioneer.*

MARKET RATES FOR OLD AND NEW PRODUCTS.

(From Lewis & Peat's London Price Current, October 9th, 1884.)

THE TWO CHIEF ENEMIES OF THE TEA PLANT.

These are the insects popularly known as "red spider" and "mosquito blight." Both have been elaborately described and carefully figured by Mr. Wood-Mason, an interesting review of whose book we quote on page 426, from the Calcutta *Englishman*. We suppose the impression was general that the red spiders of the Indian tea plantations were identical with the *acari* so well-known and unfavourably known to gardeners in Europe, being great pests, especially in conservatories. But now, after the "red spider" of the Indian tea plantations has been written about for half-a-century, we find it asserted that this particular mite is new to science and the proposal made that it should be called *Tetranychus bioculatus*. We suppose there can be little doubt that what we know as red spider in Ceylon is identical with the Indian tea mite. It seems to be less mischievous than the bug which resembles a large mosquito and which is known to science as *Helopeltis Antonii*, inasmuch as it affects the mature leaves instead of destroying the flush as the mosquito bug does, and, a long way after it, the "green fly" and a minute moth, not yet identified, which latter insect has hitherto been the chief enemy of tea in Ceylon. But *Helopeltis* is undoubtedly present, and we must only hope that his attacks on our tea may be slight and few and far between. The mites seem to have been called spiders not merely from their general resemblance to minute spiders, but from their power of weaving webs. This they seem to do as communities, the whole colony on a leaf being protected by a covering of waterproof gossamer, so fine as to be only microscopically discerned. It is startling to learn, that so effectual is this protection to the mischief-working creatures, that even the submerging of a tea estate and the coating of the bushes and leaves with mud, failed to destroy the insects or their covering! That fact disposes of the remedy of muddy water, but it is satisfactory to learn that violent rainfall clears the bushes of this puny but potent enemy. For the bug, no remedy is mentioned in the review, but we hope to find more comfort when our copy of the book reaches us. Meantime, it would seem as if the stars in their courses were fighting in favour of the pests, for, if the mites are protected by a waterproof web, the bugs are able to lay their eggs so that they are hidden from ordinary observation. Now that Mr. Wood-Mason has revealed the secret, however, we would suggest that the true remedy for *Helopeltis* is to collect and burn all shoots which show signs of being affected. A policy of this kind rigidly carried out ought surely to be more effectual than the rather dangerous remedies of fire and torches recommended in a letter to the *Indian Tea Gazette*, which we place after the extract from the *Englishman*. Strong jets of water (if liquid manure first, and then pure water, so much the better) might be dashed against trees affected by the so-called red spider: such a process might be a remedy as effectual as a natural rainstorm.

As we are writing, we receive the letter from South India, which we place below:—

To the Editor of the "Ceylon Observer."

South India, 9th Oct. 1884.

SIR,—I was about to write to you on the subject of the tea bug when Dr. Trimen's valuable report appeared. This insect does damage to so many of our products that no one can afford to ignore its existence, and information on the subject is, therefore, not merely useful, but absolutely necessary. I trust you will allow me room to ask a few questions.

1. Is the tea bug indigenous in South India and Ceylon or not? Last year I bought some Assam tea seed, and on its arrival soaked it in a strong solution of sulphate of copper before sowing it in beds. I found the tea bug in the nursery, which was in a clearing and adjoining the jungle. The beds first attacked were those nearest the jungle, and its ravages extended from them. I also noticed that a jungle plant (which I believed to be a species of Panax) was attacked in the same way, a few plants appearing in the nursery. Before planting out, I pulled off all the diseased leaves and burnt them and soaked the plants in a solution of phenyle. As soon as the heavy rains set in, the tea bug seemed to stop its attacks, and I have found not a single insect since planting, though I have noticed several leaves marked with the well-known blotches.

2. Is all the damage attributed to the real tea bug done by that insect or by any others as well? I enclose herewith an insect evidently very closely allied to the *Helopeltis*, but I cannot detect any "drumstick" on it, and it differs slightly in colour, being brown instead of black, with a triangular white patch on its back? the antennæ also, which I have unfortunately broken, seem shorter than those of the *Helopeltis*. I have found this "bug" feeding on tea, cinchona and the guava. I have also seen jungle trees marked in the same way with blotches on the leaves of the Panax above mentioned and a species of fig (*F. infectoria*). I therefore think this insect must be indigenous.

3. How large are the eggs of the tea bug? 1-10th inch long? the size of a pin's head? or smaller still?

4. I have sometimes seen cinchonas with a slit of a couple of inches long in the bark, evidently made by an insect, and once found about a dozen eggs deposited in the slit, each of them oval, flat and about 1-10th of an inch long. What can they be the eggs of?

5. Could you find out for me the names of the other two insects? One is a large bug which preys on other insects, and more especially on the oleander moth caterpillar which does so much damage to cinchona leaves; the other is a common rose beetle which often falls a prey to it.—I am, sir, yours faithfully, B.

We have no doubt Dr. Trimen and other experts will direct their attention to the questions asked by "B." Although his experience looks remarkably like the introduction of eggs of the pest with the tea seed from Assam, we suppose there can be no question that *Helopeltis Antonii* is indigenous as much in Southern India and Ceylon as in Northern and Eastern India, the insect following its instincts by developing *pari passu* with the provision of abundance of its favourite food. Unfortunately, the insect referred to by "B." as enclosed in his letter has not reached us,* but we have already indicated that the "green fly" is by many planters in India considered to be only second in destructiveness to "the mosquito blight" (*Helopeltis*). Heavy rains would seem to be as inimical to the tea bug as to the tea mite.

Dr. Trimen can probably answer the question about the size of the eggs of *Helopeltis*. From the description quoted from Mr. Wood-Mason's treatise, the eggs would seem to be almost microscopical. It seems not improbable, we should say, that the eggs found by our correspondent in a slit of cinchona bark may have been those of the tea bug. Curiously enough, the creature which in Java has been specially destructive to cinchonas has not been observed, that we know of, on cinchonas in Ceylon. As yet it has done

* Since writing this, the box of "poochies" has reached us, and we hope to report on them later on.—ED.

serious damage here only to cacao, but it is undoubtedly present on tea. As already intimated, Mr. A. M. Ferguson, junior, of Abbotsford, has, for more than a year back, noticed, on small portions of flush, marks so exactly resembling those figured in the *Tea Cyclopedia* as the work of *Helopeltis*, that he strongly suspected the presence of the tea bug But so limited was the damage done, that recently he could respond to Dr. Trimen's request for specimens with only a few leaves. When we visited Abbotsford last week, however, thorough search was instituted, and several immature insects were captured on trees where their work was apparent in spotted and shrivelled flush. The careful examination of one of these poochies under the microscope, with the coloured drawing of the creature in the *Tea Cyclopædia* present for comparison, left no possible doubt on the minds of the three persons who took part in the examination. Our readers may well believe that it was not with feelings of pleasure we recognized and announced the fact of the presence of *Helopeltis* to however small an extent. But it can do no good to conceal the truth. We only hope that the wonderful charge made against us of introducing gum-disease in 1882, because we were the first to describe it, may not now be repeated in the case of the tea bug. If *Helopeltis* exists on Abbotsford, we may take it for granted that it exists and will soon be identified on other tea plantations in Ceylon. The secretive habits of the insect no doubt account for the late Dr. Thwaites never having observed it. The same eminent naturalist never noticed the deadly coffee fungus until in 1869 it appeared on the estates. We cannot doubt that both fungus and bug are indigenous, latent until forced into action and notice by (to them) favourable circumstances. We consider it nothing less than providential, that, simultaneously with the appearance of the deadly sucking bug on our tea, has appeared Mr. Wood-Mason's book revealing the secret of the deposition of eggs in succulent shoots. Surely this will enable planters by the readiest method, if not to extirpate, yet to reduce to a minimum the numbers of these insect pests on their estates. By this time, we suppose, specimens have reached Dr. Trimen from Abbotsford of the hog-shaped insects with the long proboscis and the peculiar spike on the back, and we cannot doubt his verdict, any more than his agreement with our conviction that Mr. Wood-Mason's discovery of the mode in which the eggs of *Helopeltis Antonii* are deposited gives the tea planters of Ceylon and their Indian brethren of this generation an enormous advantage, of which they will not be slow to take advantage. Those who gather the insects, mature or immature, may be said to destroy their thousands; but those who devote to the fire holocausts of the eggs can be truly described as destroying their tens of thousands of the chief enemy of the tea plant.

THE TEA-MITE AND TEA-BUG OF ASSAM.*

A most valuable addition to the literature bearing on tea and tea cultivation has been made by Mr. Wood-Mason in the above work. Of the numerous insects that prey upon the tea plant, there are but two which are known to do such injury as materially to diminish the profits of owners of tea estates, and it is to a description of these two pests that the book is devoted Of the Tea-mite Mr. Wood-Mason says:—

"The mite lives in societies on the upper surface of the full-grown leaves, beneath an exceedingly delicate web, which it spins for itself as a shelter. This web, ordinarily invisible to the naked eye, is often rendered visible by the deposition upon it of dew in minute globules, which give to the leaves, when bathed in the morning sun, an indescribably splendid appearance of being sprinkled over with minute diamonds. I believe that this web serves chiefly as a protection to the tiny arachnids from dew and light showers, for heavy rain, especially if long-continued, breaks up the sheltering webs, and thus leads to the disappearance, if not to the destruction, of the pest."

A good deal of information is given as to the manner in which the mites lay their eggs, which they usually do in hollows, close to the ribs of the leaves, and also to the process by which the insect arrives at maturity, to the method of generation and to the means by which the mite injures the tea-plant, which it does by repeatedly puncturing the leaves and pumping out the liquid contents of the epidermis by the aid of the pharyngeal pump with which it, in common with all other arachnids, is furnished. A freshly punctured leaf exhibits a regular and pretty pattern of irregular star shaped patches of light green worked upon a dark ground. In order that the manner in which the punctures are made may be understood, the mouth parts of the insect are thus briefly described:—

"These consist of (1) a conical rostrum or beak, the sides of which are embraced and partly formed by (2) a pair of short, stout and jointed palpi or feelers which end in a pair of pincers, and answer to the great claw-bearing feelers of the scorpion and to the first maxillæ of an insect, and of (3) a pair of jaws or mandibles, which do not enter into the composition of the beak above, and in front of which they lie, but between which and them, on the contrary there exists a wide interval. The rostrum is not serrated on the edges so as to resemble that of an ordinary tick, as it is in the European *T. telarius*, but on each side of the minute slit-like opening which constitutes the mouth, and is placed at its lower extremity, it bears two minute, curved, and probably movable spines. At the ends of the short fixed arms of the pincers of the feelers open the ducts of the glands, which furnish the viscid secretion wherewith the animals spin their protective webs. The mandibles or jaws are a pair of long and delicate needle-shaped rods, which ordinarily lie retracted out of sight into their sheaths ready to be shot out with lightning rapidly. It is a remarkable fact that the sheaths, which appear to be none other than the basal joints of the mandibles, retain their primitive embryonic distinctness throughout life, and do not coalesce in adult life so as to form a single common sheath, as they are said to do in *T. telarius*. It is more probable that leaves are punctured by these mandibular needles, and that the two little movable spines placed at the sides of the rostrum serve only to keep the sucker-shaped elevation around the mouth closely applied to the wounded spots in order that the buccal pump may act as effectually as possible, than that the latter perform the double duty of lancets and retentive hooks."

The mite is described as being a very minute insect, the female measuring only about one twenty-fifth of an inch, the male being about one-sixth smaller. To the naked eye the Tea-mite appears as a dull blood-red speck, but under the microscope presents itself as a much brighter and more variously coloured object. A full description of the appearance both of the mite and of the bug is given, and there are several excellent coloured plates which show the insect very much magnified, as it appears when looked at through the microscope. The tea-mite seems to be unknown to science, and the name proposed for it by Mr. Wood-Mason is *Tetranychus biocul tus* in allusion to its double (really two pairs of) eyes. Regarding the ravages of the tea-mite the author has, amongst other remarks, the following:—

"The view entertained by many planters that this pest is carri d to gardens and distributed over them by insect-agency does not receive the least support from my observations. Moreover the analogy of the closely allied European species, *T. telarius*, is wholly opposed to such a notion, which doubtless owes its origin to the Tea-mite having been mistaken for some one of the numerous red or reddish-yellow mites belonging to totally different groups, which do commonly occur parasitically on the outside of the bodies of the most diverse groups of insects—a kind of parasitism which is of such common occurrence that I have rarely if ever sorted the contents of a bottle containing

* Report on the Tea-mite and Tea-bug of Assam, by J. Wood-Mason, Esq., Deputy Superintendent, Indian Museum, Calcutta (Taylor and Francis, London).

a mixed collection of terrestrial arthropods preserved in spirits without finding one or more individuals or even species of these parasitic arachnids, and that the least observant amongst us must have repeatedly met with instances of it. Various remedies have been suggested and tried, of which the most approved consists in sprinkling the affected bushes with muddy water. An instructive commentary on the efficacy of this remedy is furnished by the following particulars of a case in which it was applied by nature in the most perfect manner conceivable, and yet signally failed.—On one occasion a badly smitten tea-plantation suffered prolonged submersion beneath the overflowing waters of a hill-stream, the water standing high over the tops of the highest bushes for several days. When the waters had subsided the bushes were all found to be covered with a complete coating of the fine silt of which these torrential mountain-streams hold such a load in suspension, and presented, according to my informant, a truly remarkable appearance. The weather happening at the time to be dry and sunny, the coating of mud soon dried, and on the second day after the recession of the flood the spiders were as active as before, having clearly been preserved by their silken webs."

The Tea-bug is described as being a member of a genus of Capsidæ which is characteristic of the Indo-Malayan fauna, and extends in its distribution from North-eastern and Southern India (including Ceylon) through the Philippines, to Waigion and New Guinea. The author quotes the opinion of Mr. Peal as to the ravages caused by the pest. The general view of the tea is that the shoots are all brown, withered, and in fact dead, and the tea presents a generally brown look, instead of the bright, healthy green that is usual. Mr. Wood-Mason claims the credit for having discovered the manner and position in which the tea-bug lays its eggs, and his observations in this direction were published in the *Assam Gazette* in 1881; but he gives, in the work under review, a more detailed account than that which previously appeared, and he furnishes some interesting information regarding the habits of the insects and describes some experiments that he made that will doubtless be read with interest by tea planters. One of the experiments is described as follows:—

"I placed four or five virgin females in company with males in a cage with fresh tea-shoots. I witnessed the union of the sexes and the subsequent deposition of the eggs. As soon as the eggs were laid, I dissected one of them out of the shoot, and mounted it in glycerine and water. On crushing the preparation by slight pressure of the covering glass, the contents of the unsegmented ovum ran out together with four spermatozoa. I still possess this preparation, which is proved to have been made from an egg taken from a shoot, by the presence of masses of the tissues of the plant containing spiral vessels. The respiratory processes of the egg-shell so closely resemble the fine pubescence which clothes the surface of the shoots as to be quite indistinguishable from it to the unaided eye, and, to eyes unaccustomed to zoological work, even with the aid of an ordinary lens; so that it is no wonder that the planters had altogether failed to find the eggs of this pest after these had left the bodies of the females."

The book is well printed, and the coloured plates are accompanied by descriptive notices of the insects illustrated.—Calcutta *Englishman.*

MOSQUITO BLIGHT.

SIR,—In your valuable paper of the 2nd September—article "Ceylon Notes"—your correspondent writes of the Helopeltis or mosquito, which is the same pest that troubles our Indian Tea gardens, and is called the mosquito blight, the insects being *a good deal larger* than a mosquito, with long legs and proboscis.

There is but little doubt that this is the most destructive and formidable of all blights. Red spider has been much commented on though I doubt if it is *nearly* as destructive as the green-fly which is becoming most common in the Darjeeling Hill gardens, the effect of which is to deprive the leaf of its ordinary amount of sap. The leaf is small and stunted, as is the length of the flush, which would not weigh one-fourth of its ordinary weight; and this takes more than twice the ordinary time to come on, and if left on the bushes shrivels up and the buds or tips die off. No efficient remedy has been found that could be applied for this blight, up to this, that would be cheap enough. I am anxious to know if any of your readers have tried placing small pans on the garden, filled with kerosine oil, and put somewhere near the bushes affected, lighting the kerosine in the night so as to attract the insects to their destruction? I have no doubt this would be a valuable method of destroying the mosquito when mature, for it is well known how all insects are attracted by lights during the night. A muster of coolies with lighted torches, paraded in lines through the bushes, and made to pass the torches *quickly* under and around the bushes so as to avoid scorching them, would, I presume, do great havoc among the mosquito. I should say a tin of castor oil, mixed with about three or four quarts of kerosine, would be the best oil to use with the torches, as it would create a large flame, and not be so liable to be extinguished by wind. The experiment is simple, and would destroy more mosquitos than could be killed with the hand by ever so large a staff of coolies.

I would much like to know how this succeeds, and if the writer of "Ceylon Notes," or any other person, would let me know through you, Mr. Editor, or through your valuable journal, I would feel gratified, for simple as the medium is, I am sure it has not had a fair trial, *if any at all.* I do not think that the mosquito would be extirpated by it, but the attack would be *greatly lessened I feel sure.* I have seen some gardens in low-lying flats and hollows in the Darjeeling district, closed by mosquito for two or three months of the manufacturing season, and at that time I never thought of trying the plan above mentioned, or rather I should say of suggesting it, for the gardens in question were not in my charge. "GREEN FLY."—*Indian Tea Gazette.*

TEA IN AMBAGAMUWA.—No. I.

CLOSE PLANTING FOR TEA—TEA PLANTED AMONGST COFFEE—EXTIRPATION OF COFFEE AND CINCHONA TO MAKE ROOM FOR TEA—CARDAMOMS—LIBERIAN COFFEE—CACAO—TEA FOND OF RAIN WITH HOT SUN AT INTERVALS—A PERIOD OF REST NEEDED FOR TEA—WHEN TO PRUNE—FREQUENCY OF PLUCKING—THE LABOR QUESTION—DIFFERENCE BETWEEN COFFEE AND TEA PRUNING.

I take the earliest opportunity of correcting a misapprehension of what was stated to me recently regarding close tea planting. It is at a high elevation on the Ramboda Pass that such close planting as $5 \times 2\frac{1}{2}$ feet has been adopted. My informant knows of nothing closer than 3×4 in the lowcountry.

In journeying upcountry the traveller receives but an imperfect impression of the extent to which tea is planted amongst coffee, unless he specially looks into as well as at expanses of coffee, amidst a large proportion of which tea plants have been "put out." Where, as in some parts of Ambagamuwa, the coffee is old and worn out, there is no difficulty: the coffee trees being either rooted up or deprived of their primaries. In the latter case the naked stems strikingly set off the succulent growth of the tea. In other cases the coffee amidst which tea is planted is allowed to grow until the tea plants are a couple of years old, when a pretty common practice is to trim one row of coffee plants, allowing a sucker to grow up and bear a final crop or a couple of them, the intermediate rows of coffee receiving similar treatment next season. In some cases, however, the planter deems it best to make up his mind to have only the one product on his land, and so the coffee plants are ruthlessly rooted out as cumberers of the ground and the land is lined afresh for tea. The extent to which both coffee and cinchonas are being extirpated, in order to make room for tea, will, ere long, render necessary a careful revision of our statistics of various products. Clumps of cardamoms are, occasionally, curiously conspicuous, as on some estates in lower Ambagamuwa, but the limits of the cultivation of this spice cannot be very far off. The seeds, besides being used as condiments, confections and carminatives, are, I understood, largely employed in the manufacture of liqueurs. The rains which had succeeded the prolonged and trying drought had given new life to the Liberian coffee and cacao we saw from the railway, the cacaos amongst the old coffee on Moragalla, near the great tunnel, looking especially flourishing. Cacao is a most valuable addition to our products, but its range of soil and climate is limited as compared with the ubiquitous and cosmopolitan tea plant, in which the future of Ceylon is

really centred. The difficulty is to say where this plant will not grow, provided the rainfall is 70 inches and upwards to five times 70 inches. Tea is as tolerant of rain as a Newfoundland dog is of water, only the rain must at intervals be relieved by strong sunheat and bright light. Ceylon planters are coming more and more to understand the cultivation and treatment of the plant. The very word "cultivation" is used in India to designate the process of digging prunings and "jungle" (grass and other weeds) into the soil, and, strong as the temptation may be to go on, in this forcing climate, taking "flush" off plants perennially bursting into leaf, for periods extending to a year and a half, yet the gradually increasing proportion of "bangy" or hard leaf inevitably gives warning that a period of rest and recuperation must be secured by the process of pruning. In the native habitat of the plant, in Assam, there is a marked winter season extending from November of one year to the March following, and so there is no choice but to prune in November and to leave the plants in the enjoyment of what the old Book calls a sabbath, until the golden flush again clothes the naked stems in March. Although we have no marked winter in this island so near the equator, I yet suspect that the north-east monsoon period should be chosen for the operation of pruning, between November and February. But I suppose that instead of six months' cessation of picking out of the twelve, as in India, a three months' or even two months' interval will here suffice. If the picking or plucking process goes on once a week, or once in ten days as the utmost interval, and justice is done to the plants meantime in the way of cultivation, the results will be satisfactory, even if less than the hundred pounds of made tea per month, of which I lately heard, are gathered. And this leads me to mention what I heard as the explanation of the position in the London market of teas turned out by an Ambagamuwa planter, who is known to be an accomplished tea maker. I ventured to suggest "coarse plucking," and I was told that deliberately, at the risk of his own reputation as tea maker, but with the full approval of his employers, in whose interests he acts, the planter in question plucks only once a fortnight, in order to be able to employ his labour in the intervals in extending planting operations. Under such circumstances 10d per lb. may pay as well as 1s 3d to 1s 6d. But the case suggests serious possibilities of embarrassment in the future with reference to a sufficient supply of labour for the varied operations of a tea estate even after machinery has done its best, and it is really wonderful what rolling, drying, sifting and sorting inventions can accomplish. The Tamil coolies have ever been largely migratory, and the habits of the coffee, tree in bearing its harvest during a certain season of the year suited theirs It may be a question whether, in the case of tea also, the time for pruning and the period for rest may not require regulating with reference to the set times for coolies to arrive and depart. Of course a large proportion of the labour may be relied upon to remain here for several, in some cases for many, years. In regard to coffee, the Tamils, with their delicate, pliable hands and fairly intelligent brains, have gained the reputation of pruning as well as if they had been trained at Kew and they seem to have emulated their European masters in rapidly and thoroughly acquiring the art and mystery of the culture and preparation of tea. No wonder, however, if a planter feels a pang at the contemplation of pruning his beautiful and leafy tea bushes. Coffee, even after a pretty stringent course of pruning and handling, continues to cover the ground and is not reduced in height. But the contrast between an unpruned and a pruned field of tea is really shocking and somewhat depressing: witness Mariawatte at the present time. When some hillsides of tea much further up were first pruned, a neighbour from the opposite side of the valley came across in alarm to see what had become of the vanished expanse of bright foliaged bushes. They were there, but "sailing under bare poles." Tea has the advantage over coffee, however, of rapidly recovering from the action of fire.

No. II.

THE GREAT RESUSCITATOR, TEA—THE TEA FACTORY ON CAROLINA.

From the railway the grand tea factory recently erected by Messrs. Leechman & Co. gives one the idea of barracks calculated to accommodate several companies of soldiers. We stopped at Watawala to have a look at the internal fittings and working of this the largest and best appointed tea factory in Ceylon, built to serve the purposes of four flourishing tea estates, besides curing such leaf from other estates as is delivered for payment of nine cents (about 2·1) per lb., 4lb. of green leaf on the average resulting in one of dried tea.

A special road connects the highway to Dikoya with the railway station, and down this road we travelled with a deep precipice on one one side over which rolled a very fine waterfall whence power to drive the factory turbine is to be permanently derived, power which will enable it to do the work of thirty horses, or four times, we believe, what an overshot water-wheel costing the same money could effect. The turbine, too, is not open to the objection of scattering water about where damp is undesirable. Carolina is steep-featured, and the tea visible around the great store is still young, but nowhere can finer or more luxuriant bushes be seen than on Agrawatte and Kadawella including some fine indigenous. From these properties much valuable seed has been seasonably supplied for the extension far and wide of the new and promising industry. Withering, rolling, fermenting and drying operations were in full swing, as we approached the factory from which emanated that pleasant malty flavour so characteristic of fermenting and drying tea. Our first impression on entering was connected with the vast space and the perfect arrangements for light and ventilation, all the numerous cross-passages and glazed windows facing each other. The K. A. W. Central Tea Factory, Ambagamuwa, was erected by Mr. W. Megginson after plans (from Mr. M's. design) carefully prepared and furnished by Messrs. John Walker & Co. The total cost was no less than R35,000, but it is anticipated that in three years' time the whole of the cost will be repaid by the facilities afforded for manufacture. To the courtesy of Mr. Megginson we were indebted for the following interesting details:—The building is of wood on finely-dressed stone pillars. There are three floors, the total height from ground to ridge being 42 feet. Another story can be added when required and there is ample room on the levelled space for spacious wings. The space from centre to centre of pillars is 15½ feet, the timber being consequently very massive. An elephant was constantly employed for nearly three months removing the posts and beams from the estate jungles. The ground-floor is one even sheet of cement ¾ inch thick on the top of 4 inches of cement concrete. This floor measures 130 feet by 50 feet, and constituted one of the most costly items in the building, but the expenditure to secure a firm, clean floor was wisely incurred. This ground-floor room is 10 ft. high beneath the beams, and is lighted by 50 glass windows 5 ft. × 3 ft. This room is used for manufacturing, for sifting and sorting and packing. The two upper rooms are lighted by 36 glass windows

same size as in the ground-floor in each and the room each measures 124 ft. × 31 ft. and have boarded floors. These two rooms are used solely for withering, and have withering space for 8,000 lb. green leaf. Nothing in truth could be more perfect than the arrangements for the important process of withering. The machinery was supplied and erected by Messrs. John Walker & Co. First there is the turbine of 30 horse-power, as we have already indicated; an *Excelsior* roller and a *Challenge* roller, a Kinmond drier and a Sirocco. The mode in which the Excelsior roller dealt with successive feedings of leaf was all that could be desired. Means are already provided for manufacturing 200,000 lb of tea per annum, and it is estimated this amount will be made next season. With additional withering space, which can easily be supplied, and with more machinery for which space and water-power are already provided, the factory would be capable of turning out 400,000 lb. of made tea per annum, which amount, it is estimated, will actually be manufactured a few seasons hence. The total outlay on the factory and fittings, the machinery and a long watercourse to the head of the Carolina falls, a 12 ft. cart-road nearly half a mile leading to the Government road, a bungalow, two conductors' houses, lines for factory hands and a central rice store amounts as we have indicated to R35,000;* which sum will quickly be paid off by the saving effected in centralizing the saving of machine manufacture over hand, the extra value of the tea from its being "factory bulked" and dispatched in frequent large breaks and by a small profit on purchased leaf. We may add that leaf is being received at 9 cents per lb. from seven estates *besides* the four estates constituting the K. A. W. group.

If anyone had predicted ten years ago that the progress of the tea enterprize would be such as to demand and justify the erection of such buildings and the provision of such machinery for one group of estates, we suspect he would be deemed wildly sanguine; but Messrs. Leechman & Co. have combined prudence with boldness in making such ample provision for the harvests of tea leaves which their portion of Ambagamuwa will yield,—*is* yielding, in truth, and we feel confident that the great Central Tea Factory on Carolina estate near Watawala station is but the precursor of many such erections, not only in Ambagamuwa, but in all the planting districts of Ceylon, lowcountry and high, which the rapid progress of the tea enterprize will necessitate. The duty of Government is also to adopt a policy of combined wisdom and boldness, by *everywhere* providing facilities of transit for the new product and all the labour and commodities which its culture and manufacture will demand

TEA, CINCHONA AND COFFEE IN AMBAGAMUWA AND DIMBULA.

(From an old planter.)

FROM THE LOWCOUNTRY TO THE HILLS—GAMPOLA AND NAWALAPITIYA IN THE OLD DAYS—CHANGE DURING THE LAST 15 YEARS—COFFEE AND TEA—UNCULTIVATED LAND—SOIL AND CROPS IN DIMBULA—THE COFFEE CROPS OF YORE—THE COFFEE LEAF FUNGUS—ASCENT OF RILAGALA IN 1847—THE VALLEY OF DIMBULA—HOPE FOR THE FUTURE—ON THE HILLS AND IN THE LOWCOUNTRY—CINCHONA—QUININE MANUFACTURERS—THE HAPUTALE RAILWAY.

After an unbroken residence of over a dozen years at altitudes not exceeding 300 feet, I very gladly accepted an invitation to visit Lindula, with the further favour of being franked there and back; a necessary condition with a poor old *buffer*, whose heart is much heavier than his purse, and who is neither an entertaining nor instructive companion, so that my entertainer can have little return for the outlay, unless, indeed, it should give an ultimate return as a commercial investment, of which there is some reasonable hope.

When the train reached Peradeniya, I was on known ground, for, during a residence of fourteen years in the Masnawatte Valley, I made at least one hundred and twenty journeys to Kandy and back. I remember Gampola when there was only a thatched resthouse and a few Sinhalese kadies, and Nawalapitiya when the sole resident was an old Moorman that kept tavalam-cattle to carry rice from Gampola to the infant coffee estates beyond. As fifteen years have elapsed since I last visited those regions, the changes were very remarkable. Fine coffee fields had been restored to nature, and places abandoned twenty-five to thirty years ago were become fine tea-gardens; but the bulk of the cultivated land of thirty to forty years ago is covered with mana grass, and the tea fields are chiefly on new land, though in a few places trial is being made of the long-abandoned coffee fields, the success of which is rather to be hoped for than expected. No coffee property in Ambagamuwa ever paid back the capital spent in establishing it, even in the *ante-Hemileia* days; but it seems now fully proved that tea may be profitably grown, even on spots where coffee was early abandoned; whether the land that coffee was taken off, as long as there was any to take, can be utilized for the new product with a profitable result, is not yet an established fact. Indeed, there is much of the land through which the railway passes between Galboda and Hatton that would not grow a profitable crop of any economic plant with which a pretty wide experience has made me acquainted.

In passing from Hatton into Dimbula by the Nuwara Eliya road, the region of slab rock is left behind, and the soil progressively improves in depth and quality right up to Nanuoya station and beyond, where, in many places, there is soil of good and uniform quality, ten feet deep and more. There is still coffee in Dimbula and Lindula as fine as I have ever seen, but, alas, for the crop! Very fine trees without a speck of fungus; yet it required a close inspection to detect the few fruits that nestled among bright foliage. What a contrast to the crops I had to do with in Matale East thirty years ago, when a single primary branch of three years old coffee yielded five hundred ripe cherries, thirty-five of which were picked from the base of one pair of leaves! There is very little fungus on the coffee at present, but it has left its mark deeply impressed on many a once flourishing field, and many a clear-headed, hardworking man has been brought to ruin by an agent that on its first appearance looked so insignificant. Much has been done by way of retrieving the terrible disaster. Cinchona has been grown by millions and tea is being planted by tens of millions, and, if there is only sufficient capital forthcoming, Dimbula will in a few years yield larger profits in tea than it has ever done in coffee.

In 1847 I organized a party to watch the sunrise from the top of Rilagala. I cleared a track through the nilu, and discovered a comfortable cave to pass the night in about 100 feet below the summit. With early dawn, we were at our post and overlooked the whole valley of Dimbula, and its subsidary offshoots, an unbroken sheet of forest but for one tiny spot, which is now, I believe, known as Radella. At the end of nearly thirty-seven years, I looked down on the same scene from the top of Abbotsford. What a change had been wrought! Hardly a tree of the original forest remains between the two points of view, and all the space between spread out like a map, showing a vast field of 50,000 acres of cultivated land that must have cost well nigh two millions sterling and which, had no blight fallen on it, would now have been yielding its proprietors an aggregate income of three to four millions of rupees, giving a comfortable living to forty thousand people and contributing directly and indirectly well-nigh two million rupees to the colonial revenue.

There is hope as near a certainty as any future event can well be, that the depression under which the planting interest now suffers will pass away in a few years, and that the new product that has found a congenial home in the colony will restore the prosperity that raised it to so high a place among the outlying possesions of the British Empire. Some of the Dimbula proprietors are already reaping the advantages of an early acceptance of the situation created by *Hemileia vastatrix*, in profits from tea greater than were ever expected from coffee on the same land. We can put our tea into the market ten cents per pound under the India average, and converting a

coffee into a tea field is a comparatively inexpensive operation.

I have now seen perhaps the finest tea fields in the island, but I have seen no growth of the same age to equal that on this place, about 300 feet above sea-level. I do not however deceive myself as to the comparative value of an acre of tea in Lindula, and the Siyane Korale: the former will probably be as good a century hence as it is now; the latter will, with equal probability, require manure in less than a decade if it be found that manuring will then pay. There is little doubt that ten years hence the price of tea will be so low that only large crops and low expenses will enable producers to keep the field, and in this respect Ceylon has a decided advantage, but our lowcountry soils are not inexhaustible, however forcing the climate may be. A leaf crop is less exacting on some of the elements of fertility than a fruit one, but that which it does require is not in unlimited supply on the great bulk of our lowlands.

Cinchona bark has become, for the present, more of a drug than ever, but it is far from being a defunct industry. A period of low prices fosters demand for a product that has an expanding market. In this case, the small body of quinine manufacturers have thought it more to their interests to combine against the producers and the consuming public than to let competition have free scope; but where capital is free to seek the most remunerative investments, the artificial enhancement of the price of the manufactured article, as compared with that of the raw material, can only be temporary, and there is a good time coming for cinchona planters who can afford to wait.

PLANTING NOTES FROM BADULLA, (CEYLON).

THE WEATHER AND CROPS—VICISSITUDES OF COFFEE ESTATES—A BELIEVER IN COFFEE.

Picking of autumn crop is going on fairly, some estates getting as much as one and a-half box per cooly per diem. The sample is turning out pretty fairly on estates above 3,000 feet elevation. Not so much light coffee as might have been expected after the long-continued drought of this year; ten per cent would about represent the average of light coffee, but beyond this a good proportion of *deficient* beans and triage will be found after the parchment goes through the hands of the Colombo "peelers." I once heard it said, and that many years ago, that we planters only "skin" the coffee upcountry, but the "peelers" doubly skin it in Colombo, meaning that they take off both parchment and silver skin; but that this implied or meant a little more, many a poor struggling proprietor learnt to his cost when he got "the peelers'" account and looked into his crop account at the end of the year. Tea planters of a future generation may thank their stars that they won't have a peeling account, but let them take care that they are not all rolled into "dust" by too many brokers here and at home.

I see that you have quoted from your morning contemporary "the vicissitudes of Gomera estate in the Kunekles," which I have no doubt went through many a skinning, peeling, and whittling account in its day, which helped to bring that fine estate on its last legs. That the soil is not to blame for the collapse is evident by the new purchaser giving R20,000 for the land in order to turn it into a tea garden I cannot help thinking that these celestials' ideas of exhausted and washed-out coffee estates making fine tea gardens will end in poor mortals' moonshine and that many a proprietor will run the day he dug out his fine coffee bushes to make place for the mania "tea." I see some estates round here doing this on a somewhat large scale. I am still the humble servant of and firm believer in old King Coffee, and that it will still pay and pay handsomely too, if it is only faithfully and generously served and tended. As an illustration and reason for my faith in coffee paying well, I will mention, not "the vicissitudes," but the *certain success* of Ury estate, the property of the late Mr. George Morice, who died a few months ago leaving a valuable property and several thousands of pounds to his heirs. The late Mr. Morice, as you are perhaps aware, arrived in Ceylon a very poor man in the year 1842. After years of hard toil on the Kandy side as an assistant superintendent, he came up to Uva in 1856 or 1857 and opened Glen Alpine estate for Messrs. Brown and Stewart, annually laid by a portion of his small salary, and a few years after, in partnership with his employers, bought a piece of land and opened it as Ballagalla estate, the third share of which he sold again in 1863 for R18,000, and, retiring from the partnership took employment under the Messrs. Worms and planted Keenakelle estate, and, when these gentlemen sold all their property in the island, he took charge of Wewesse and Debedde, the property of Mr. Cowasjee Eduljee, on a moderate salary and commission on crop. these properties afterwards being sold to Mr. Woodhouse for R400,000. In 1869 Mr. Morice bought another block of land, and opened Ury estate, *the very year when leaf-disease first made its appearance on Galoola estate in Madulsima*, and to which pest have since been attributed all the curses and misfortunes which have befalleu coffee estates. At this time (1869) Mr. Moriee had by great frugality and thrift laid by a sum of about R30,000. With this capital in hand he set to work, never borrowing a cent from agents or anyone else, and, for the last eight or nine years of his life, lived on and managed (in the right good old style) his own property, clearing an annual profit of R10,000 to R15,000! NEVER MAKING A LOSS from the day the estate came into bearing! Besides a sum of "ready cash" in the hands of his Colombo agents, he has left Ury estate uncncumbered, there being 200 acres of fine coffee and cinchona of the oldest and best trees in the district, and another 200 acres forest and patana. Value the property at what you like, all I wish to point out by the above account is, that coffee estates, even with leaf-disease, no manuring and dear transport, even in this district can be made to pay by GOOD MANAGEMENT, provided one can steer clear of agents and mortgagees, "necessary evils" they have been to those who have unfortunately dropped into their hands. In this respect a warning should be got from the way in which money was scattered about in 1875-8, bankers lending money often to men in buckram, speculators, and inexperienced young men, who did not know the difference between a coffee tree and a gooseberry bush!—many of them given to riding about the country in knee-breeches and kid gloves, swilling champagne at meets and jymkhanas, lawn tennis and cricket matches, neglecting their work, ruining their health, losing their employer's, and sometimes their own, time and money—in fact, doing anything but learning coffee planting and how to make it pay. If tea planters were to adopt the same lines and follow the same amusements, their end would not be far of, and the grand profit of 1d or 2d per lb. more prove a visionary hallucination. But they are learning in a different school.

COFFEE PLANTING IN UVA (CEYLON): HAPUTALE RAINFALL AND THE PROPER TIME FOR PRUNING COFFEE

The number of days on which rain fell in Haputale for 13 years from 1st June to 30th September:—

§ Coffee suffering from effects of dry weather.
‖ Two distinct shocks of earthquake on 19th and 25th.

The above table may be of interest to your readers, as it proves that the past four months have been, as described by your correspondents, one of the driest seasons they can remember. and the result will be good crops from the upper fields not overburdened with crop last year.

With the above table before you, the question naturally arises, why should there be such a falling-off in 1877, that is, crop 1877-78? Simply because the wet weather in September was so continuous and severe, that, instead of blossom, we had a tremendous quantity of young wood out, which had to be removed, and thereby threw the trees into heavy blossom in March; the trees have not recovered from the effects of the change. If this state of affairs applies to Haputale low places generally, it would be well if some of your able correspondents would come forward with their opinions.

Although I am not an authority on pruning, nor have I any patent process for overcoming the effects of leaf-disease and change of seasons, yet perhaps it may not be out of place to say here, that, if it could only be shown that a liberal allowance for pruning is more frequently than otherwise attended with good results, even in these times of short crops, more attention and money would be bestowed on it. Methods of pruning are so various that I have no desire to raise any discussion on this point; but *the time* of knife-pruning, so far as practicable, should be from January to middle of March, to throw the crops more into spring, as the spring crop is not so liable so the same percentage of light as the autumn. For autumn crop, knife-prunning in June, July and August gives wood and blossom in the following spring.

I quite sympathize with an Indian correspondent who was lately complaining that discussions as to coffee culture have been supplanted by tea. This ought not to be. We have valuable coffee, and it requires more culture now than ever, and it will revive if a little more consideration and kindness be shown towards it.

PLANTER

THE GOVERNMENT OF INDIA AND CINCHONA CULTURE.

We take from the *Times of India* a very interesting *résumé* (given below) of a series of papers which have been issued on the growth of cinchonas and the manufacture of febrifuges on behalf of the Indian Government. The stocks of alkaloids in London seem to have accumulated, and the very proper step is to be taken of distributing febrifuges cheaply amongst the people of India. Although a large percentage of alkaloids is lost by manufacture in India, it is yet held that the fact of such manufacture being carried on reduced the cost of quinine in the market and enabled the Government of India to supply a cheap febrifuge to the masses of the people. A fierce controversy has raged about the question which is not yet settled. As to the present glut and low prices, no doubt, Professor Lawson is correct in stating that a change will soon take place. We hold now, as we have ever held, that the Government of India by information imparted has done more good to private planters than their competition has done harm. But the questions of manufacturing alkaloids in India or London, or buying in the open market, are certainly open ones.

THE CULTIVATION OF CINCHONA.

An interesting set of papers relative to the position of Government respecting the cultivation of cinchona has just been issued by the Government of India. The papers include a valuable report by Mr. Danvers, of the India Office, tracing the history from 1860, when Mr. Markham first opened a cinchona plantation for the Government at Ootacamund. In 1863 the success already attained warranted sanction being accorded for extending the plantation, at the rate or 150 acres yearly. All barks were sent home for sale until 1866, when a quinologist was appointed, and the manufacture locally of the febrifuge undertaken. The first results reported were highly efficacious, but in 1871 the question as to the propriety of the State maintaining these plantations was raised. It was decided to continue them as heretofore, but not to manufacture locally, all bark being instead sent to London. The growth of cinchona expressly for sale in London being the deliberate policy of the Government. In 1875, however, Mr. J. W. B. Money, a cinchona planter, wrote to the Secretary of State complaining of the Government interfering with trade. He urged withdrawal, as the Government had, he alleged, assured the planters that it would not compete against them, and finally offered to buy up the Government plantation. On reference, the Government of India stated that it had no cognizance of any such assurance, but recommended that for the present the Madras Government should direct its efforts chiefly to establishing a local manufactory for a cheap febrifuge, and should restrict their despatches of bark to Europe to small parcels, in view to gauging practically the prices ruling in London, and not as a commercial speculation. But as the bark was still sent home, the Secretary of State in 1878 remarked that to continue this practice merely for commercial purposes, and so to compete with trade, was to go altogether beyond the purposes for which the Government plantations were established. On receipt of this despatch, the Madras Government appointed a committee to consider the matter. The committee reported that it considered the sending of the bark was not only free from objection itself, but had contributed more than any other circumstance to the embarkation of private enterprize in the cultivation of cinchona. The Madras Government adopted this view, and urged that the local manufacture into febrifuge was not practicable. In 1881 Captain Price, M. P., asked in Parliament whether it was a fact that the Indian Government was exporting large quantities of cinchona bark to London, and whether in introducing the cinchona plant the Government did so to encourage private enterprize, or to compete with private trade. Lord Hartington replied that the object of Government in introducing the cinchona plant into India was to provide an abundant supply of cheap febrifuge for India. It was not found practicable to manufacture in Madras, and hence the bark was sent home, but that an experiment was being tried on a large scale to manufacture bark in England and if successful sales would be discontinued. The sales were discontinued accordingly, and all barks received were handed over to the manufacturers; the outcome being sent to India in response to annual indents. But the accumulation of the several preparations from cinchona has largely increased, and continues to exceed the annual demands. The disposal of these increasing stocks becomes a matter of importance as the following figures show:—

	Amount in Store. lb.	oz.		Average annual supply to India. lb.
Quinine Sulphas ..	3,660	2	...	1,482
Liquor of Amorpheus Quinine	644	0	...	84
Cinchonidine Sulphas...	100	8	...	383
Cinchonine do ...	39	11	...	578
Do. Alkaloid...	251	0	...	32
Cinchona Febrifuge ...	7,576	8	...	nil
Mixed Tartrates	218	4	...	11

As tending to reduce stock it was recommended that the manufacturers, Messrs. Howard & Sons, be paid in bark, and that the local sales of bark in Madres be tried. Before giving effect to these recommendations the legal adviser to the Secretary of State was asked whether the free action of Government in this respect was in any way restricted by the provisions of 3 and 4 Will. IV., chapter 85 (the Company's Charter Act of 1833), so far as they related to the transaction coming within the designation of commercial business. He replied thus:—"It seems to me that the provisions of the Charter Act of 1833 have nothing to do with the matter, the East India Company as the governing authority being defunct." He further added:—"I can see no reason in the complaint against the growth and sale of cinchona by Government. It is a question of policy and not of law, and stands on the same footing as the sale of Government forest timber and other products of Government lands." This difficulty being thus removed, and the absence of factories in India supporting the advisability of sending bark home, matters remained

undisturbed. The factories in Bengal (Sikkim Cinchona) only obtained 50 per cent. and the Neilgherry factory 64 per cent. of the alkaloids from the barks, while Messrs. Howard obtained 100 per cent. It is, therefore, beyond question that to Government it is financially more advantageous to dispose of bark in London than in India, as the febrifuge sold here virtually loses half its commercial value in manufacture. In forwarding the minute, of which the above is a *precis*, the Secretary of State informed the Government of India that he had under consideration the question whether it was desirable to place upon a permanent footing the existing system of manufacturing in London, and asked what should be done with large existing stocks. The question of the local manufacture of Sikkim febrifuge has been referred to Professor Armstrong, and Professor Lawson will doubtless be required to submit a similar report on the Neilgherry produce. Pending final settlement the Secretary of State proposes to revert to the former system of sale by auction of the bark sent home from India. From the large stock at home the Secretary of State proposes to send to India the quinine and febrifuge, and suggests that the latter be distributed freely at a low price in malarial districts, in view to making its value widely known. Professor Lawson, with reference to the general question, reported that although the market is at present nearly glutted, still in a few years' time there may be not only no increase, but even a considerable decrease. His reasons are that many plantations have been badly selected, and the result of the crops must prove failures. Also that the present fall in prices now prevailing will deter persons from opening out new plantations or will induce present cinchona planters to turn to more paying products. He accordingly urges the establishment of a local factory, either by private speculators or by Government, or by Government assisting capitalists. The suggestion of the Secretary of State to distribute the febrifuge at a low price will develope a large demand which Professor Lawson would meet by local manufacture in future.

The Government of India has accordingly adopted the Secretary of State's suggestion, one-half of the stock of febrifuge being sent to Bengal, and the remainder being divided between Madras and Bombay.—*Times of India.*

OUR TEA PRODUCING COUNTRIES.

The war between France and China brings into prominence our other sources of supplies for tea. The object of this article is to place before our readers as succinctly as we can some few particulars and statistics of the tea production of India and Ceylon. A quarter of a century ago some small consignments of Indian tea were placed on the London market, amounting in all to about one week's supply at our present rate of consumption. At first, from their great strength and astringency, they were rather cautiously received, but they rapidly grew in favour among our leading dealers. Through the price being so high, and the quantity so extremely limited, they were unable to be used in any but the highest-priced blends, and then only in small proportion. During the next ten years the supply gradually but surely increased, until in 1870 it reached 13,500,000 lb. per annum. From that date the "tide of affairs" of tea seems to have changed. Indian growths got more and more into popular favour, and the increasing supplies were all taken for home use, to the great detriment of the China trade; for, although the consumption of tea has gradually gone on increasing with our increased population, and was last year 46,000,000 lb. more than thirteen years previously, the consumption of China tea has remained perfectly stationary, or fluctuated only some 1 or 2 per cent. As we see from the subjoined figures, in 1870 the proportion of Indian to the total amount of tea consumed was under 10 per cent., in 1880 it had risen to 28 per cent., and last year to 34 per cent., the increase being more marked in the past than during any previous year.

	China.	Indian.	Total.
1860	75,600,000...	... 1,200,000...	... 76,800,000
1870... ...	112,380,000...	...13,500,000...	...125,880,000
1880... ...	111,307,000...	...43,800,000...	...155,107,000
1883... ...	114,950,000...	...59,097,000...	..174,047,000

Having thus attempted to show the results by actual figures, a few words may be added as to the principal causes which have led to such a state of things. First and foremost, because of the great superiority, both in strength in all sorts and great flavour and quality in the finer kinds of Indian, notably those from the Darjeeling district; teas from some of the more favourite gardens being much sought after, and very long prices paid for the finest pickings, several of the large retailers giving unlimited orders to their brokers to secure them some particularly choicelot. Secondly, because of the gradually increasing inferiority of China teas and the "poor value" the better kinds show when compared with the rival teas at the same price. It would thus appear that the consumption of Indian tea will only be limited by its supply, and, so soon as we get a sufficient quantity, China tea will gradually but surely disappear from our home-consumption.

Having thus far treated only on Indian teas, we must proceed to notice a very formidable rival, both to India and China, but more particularly the latter. During the past two or three years small but increasing consignments of tea have been imported from Ceylon, where the unremunerative state of the coffee trade, induced by blight and other causes, led the planter to turn their attention to tea-planting with every marked and considerable success, the soil and climate being especially suited to the free cultivation of the plant. Two years ago the amount exported was about 250,000 lb. This year is expected to reach nearly 3,000,000 lb., and there is every prospect of a similar rate of increase in the future, for, as a writer in a recently published article on the "Prospects of Ceylon" states, "at a not very distant period we shall have 150,000 acres under cultivation, with an annual export of 60,000,000 lb." Remembering what India has done, and bearing in mind the unrivalled climate and all the great facilities for labour and transit in Ceylon, this does not by any means seem an exaggerated statement. All the teas coming forward at present are eagerly competed for, and rapidly go into consumption, one great desideratum of this kind of tea being that it can be drunk, in its pure state without any blending or mixing with other kinds, and at a moderate cost to the consumer a very good article can be supplied. One great feature both of Indian and Ceylon teas is in the sorting, and the public are fast beginning to appreciate the great advantages obtained in using what are techuically known in the trade as "broken" or "semi-broken" teas, finding that in these descriptions they can obtain the finest teas at less money than they would have to pay for a "whole leaf." In fact, some of our large manufacturing and mining districts there is a large consumption going on of Indian tea dust, which is retailed about 1½d per oz., and thoroughly liked, although in appearance it bears a strong resemblance to coarse, dry snuff. As was to be expected, in all these gradual changes in the tea trade the larger towns have led the way, chiefly those in the north of England and in Ireland, where comparatively higher prices are paid for tea by the factory hands and working classes generally than in the smaller and more exclusive towns in the south and west of England; but, as we observed above, it is after all only a question of supply, and, so soon as a sufficient quantity of tea is imported from India and Ceylon, so surely will China tea go out of consumption, or will be only purchased where price is a *sine qua non*, as among the so-called "giving away" or "present" shops which have sprung up of late years in so many of our towns and villages. —*Morning Post.*

AGRI-HORTICULTURAL SHOW AND INDUSTRIAL EXHIBITION, KANDY, 1885.—We have received a prospectus of this show, containing the names of the committee, the regulations, and the list of prizes. The Exhibition will be held at Kandy about the latter end of May 1885. It will occupy two days, and will be opened on the first day at 2 p. m., and on the second day in the morning. Intending exhibitors may be relieved to know that the Royal Botanic Gardens will not compete for prizes. The following are the classes :—I. Garden Perennials (in pots); II. Garden Annuals (in pots); III. Ferns (in pots); IV. Foliage Plants (in pots); V. Cut Flowers; VI. Vegetables; VII. Fruit; VIII. Native Products; IX. Estate Products; X. Arts and Manufactures.

THE GOVERNMENT CINCHONA ENTERPRIZE IN JAVA: ANNUAL REPORT FOR 1883.

From the elaborate report which has been translated for the *Tropical Agriculturist*, it will be seen, that, notwithstanding a period of drought and a local storm of some violence, 1883 was a year favourable to cinchona culture in the Dutch colony. *Helopeltis* is only incidentally noticed by Mr. Van Romunde, in connection with a plentiful supply of labour—so plentiful indeed that work was *found* for the women and children in collecting the bugs. A favourable opinion is not expressed of new kinds of cinchonas recently introduced, and clearly the tendency is to confine cultivation on the Government gardens to Ledgerianas and succirubras. A superior hybrid, however, of vigorous growth and yielding 10 per cent of pure quinine, had naturally attracted much attention, and it was to be multiplied by cuttings. It is not expressly stated that the hybrid in question is one between Ledgeriana and succirubra, but we suspect that it owes its origin to the union of the pollen of these plants. In due time, however, we shall have reliable information as to the results of hybridizing operations on a large scale, which evidently present no difficulty in Java. What is quite familiar to us in Ceylon has happened also in the Netherlands India plantations, some of the hybrids between Ledgerianas and succirubras leaning to one parent and some to the other. We cannot doubt that Dr. Trimen will secure for this colony cuttings of the wonderful hybrid referred to, as well as some of the grafted plants of best kinds of Ledgerianas, which the Java Government had been selling at 10 florins upset price each, the sales of seeds and plants having, last year, realized an appreciable sum. There had been quite a rush, it seems, by private planters, for land suitable for cinchona culture, but the enterprize had been checked by the unwillingness of banks and capitalists to advance on the security of cinchona estates. We need scarcely say, that, if confidence was thus lost in 1883, it is not likely to have been by any means restored in 1884. Confidence in the coffee enterprize will next, we suspect, be shaken in Java, for the main reason adduced for a good supply of labour for the cinchona plantations was the short coffee crop. Leaf-disease is telling in Java as well as in Ceylon, and unremunerative prices, the result of the concentration of slave labour on coffee production in Brazil, have put the climax to the depression of the coffee industry in the Dutch as well as the British colony. As far as cinchonas are concerned, it is more than ever evident now, that only the culture of the best and most robust kinds will pay. *C. officinalis* does not flourish in West Java, where the principal Government plantations are situated, but our readers will observe that the bark of this kind sent for sale in Holland came next to Ledgeriana bark and not far behind it in price. Grafting succirubra plants with scions of Ledgeriana in the open, which has been such a success in the hands of Mr. Wm. Smith on Mattakelly, Ceylon, has been finally abandoned in Java, the attempts made having resulted in almost complete failure; long periods of drought, probably, accounting for the want of success. But grafting Ledgeriana scions on succirubra stocks under double glass is energetically and successfully pursued. The report speaks of all the inferior cinchonas, including Calisayas of various kinds, being rooted out, and the ground being prepared for replanting with succirubras and Ledgerianas. To shew how largely this latter, the king of all cinchonas, preponderates, we need merely mention, that, out of two millions of plants in the open, three-quarters of a million were Ledgers, and over a million of the same species were in the nurseries. Succirubras are grown in Java, not only for the yield of druggists' bark they afford, but also for grafting purposes, and for supplying officers of the Forest Department with shelter plants for the more delicate timber tree seedlings. We do not suppose the big-leaved cinchonas have ever been applied to such a purpose in Ceylon? Readers here interested in cinchonas will watch with interest the topping experiments being carried on in Java, so as to obviate the inconvenience and expense of removing bark from tall trees by means of ladders. None will be surprized to learn what Mr. Van Romunde states, that the cinchona plantations which were thoroughly trenched during the dry weather showed an immense improvement in the healthy and vigorous growth of the trees as soon as the monsoon rains commenced to fall. There is much abandoned coffee land in Java, with enormous unpruned trees on them, covered with ferns, mosses and orchids. It is interesting to learn that such lands are to be cleared for the purpose of experimenting on the growth of succirubras in the soil. Where cropping has ceased for a score of years or more, we cannot doubt the success of this experiment, although, as cinchona belongs to the same family as coffee, probably it might be better to plant up such lands with cacao or tea. Practical planters will note that the shaving process in Java is applied to only half the circumference of the cinchona trees, and that that dealt with the trees do not seem to suffer, when left uncovered. We see it incidentally stated that the cuprea bark trees grow well at all elevations in Java. These are the trees (not true cinchonas, although their bark yields similar alkaloids), the produce of which commenced the glut and depression which the enormous supplies of true cinchona barks from Ceylon completed. It seems hard that in the growth of sugar, of coffee, of cinchonas, the planter should work not for his own profit but for that of the consumers. But we cannot doubt that better days for all these products are at hand. The Continental nations will get sick of paying large sums to provide the British with cheap sugar; slavery cannot much longer exist in Brazil; and Ceylon cinchona bark has spoiled the trade of the American bark collectors. Nor can there be any doubt, that the present low prices of quinine and the other alkaloids will permanently and largely increase the consumption of the best of febrifuges and tonics, the true remedies for opium-eating and laudanum-drinking.

The interesting report on which we have been commenting will well repay perusal, even at this period of depression in the cinchona enterprize. The swing of the pendulum towards profitable prices must be close at hand.

We cannot conclude without drawing special attention to Mr. Van Romunde's confident expression of belief, founded on experience, that constant gathering of *Helopeltis* was likely to render injury from this insect a thing of the past. Just as the Java Report is ready for the press, we have received Mr. Lawson's first Report on the Nilgiri Plantations, the information in which will be summarized for the benefit of our readers.

Helopeltis Antonii IT TURNS OUT, IS A CEYLON INSECT figured, described and named by the French entomologist, Signoret, a quarter of a century ago! We shall adduce the evidence for this statement later on, with further details respecting the tea bug.

COFFEE PRODUCTION IN BRAZIL.

The Centro da Lavoura e Commercio has recently forwarded 30 packages of coffee to the International Hygienic Exposition in London, and 40 packages to the International Cotton Exposition in New Orleans. The perseverance of the Centro in seeking to make the Brazilian product more widely known is certainly a thing to be commended, and under favourable conditions will unquestionably result in some advantage to the Brazilian producers. But, at the same time, we can not help thinking that the time and effort of the Centro might be employed to much greater advantage to the country at large. It is idle, perhaps, to expect an association of coffee factors and producers to take an interest in other products, however essential and urgent such a diversity of industries may be; but even within their own special industry they are overlooking some of the most important factors in its profitableness and development. So far as we have been able to judge, the Centro's propaganda has been confined wholly to the marketing of the product, and that at times when the consuming markets of the world are largely overstocked and prices are unprofitably low. Every one knows that production is steadily increasing and in a ratio greater than consumption. The natural result of such a state of affairs is falling prices, which will remain at a low figure just so long as production continues to lead consumption. In such a state of affairs, it may be wise to seek new consuming markets for the surplus of production, but that certainly is far from being the only or even the best remedy to be adopted. Brazil can find and open no new consuming market which she will not be compelled to immediately share whith other producers, because she is there meeting them on neutral ground. With the matter of greater cheapness of production and cheaper and better facilities for marketing, however, the case is very different. Brazil ought and can produce coffee more cheaply than any other country in the world. In a great measure, however, her processes of production are antiquated, wasteful and expensive. The soil is indifferently cultivated, rarely fertilized, and speedily abandoned. The trees are rarely, if ever, trimmed, and no pains whatever are taken to develop and sustain their best bearing qualities. The result is that the product is less than what it should be for the area and number of laborers employed. Then the processes of picking are generally wasteful, and those of preparing for market are still far more expensive than they should be. Then take the excessive costs of transportation to the seaboard, the multitude of petty charges and commissions incident to marketing, and, lastly, the general and provincial export taxes, and we have abundant causes for the exeessive cost of the product wholly within the country. Instead of seeking notoriety and decorations through exhibiting Brazilian coffee in foreign markets, the Centro and its friends can do a far more valuable service to the producer by seeking to remove burdens and unnecessary costs at home. That done, there will be no need of any propaganda abroad, for the cheapness of the product will be all the advertisement it needs.—*Rio News.*

CINCHONA:

REPORT ON THE GOVERNMENT CINCHONA ENTERPRIZE IN JAVA FOR THE YEAR 1883.

By R. VAN ROMUNDE, Director of the Government Cinchona Enterprize.

(*Translated for the "Ceylon Observer."*)

1. *Weather.*—The year 1883 was marked by a large number of dry days. At the end of February a drought, very unusual for that month, commenced, which continued until the latter half of March. The proper east monsoon set in at the end of April and lasted until the middle of October. The dry monsoon was of very long duration, but from time to time several refreshing showers of rain fell: at the end of August and beginning of September indeed there were a number of rainy days. Night frosts and strong east winds, which generally accompany a drought, were not experienced. At the end of January a severe storm took place on all the estates. At Nagrak the storm caused a considerable amount of damage to plants and buildings. The storm was so violent, that a large number of the glass panes of the propagating-house there were blown in. On the other estates, however, the damage was of less account. The weather was on the whole very favourable for the Government enterprize. The drought was not conducive to the production of second crops, so that labor was plentiful and the harvesting and drying of bark underwent little or no interruption.

2. *Propagation.*—The number of plants in the open at the end of the year amounted to 1,966,500. Of these, 100,000 are cuttings and grafts of *C. Ledgeriana* and 635,500 Ledgeriana seedlings. In the nurseries there were found on counting to be 1,059,000 Ledgerianas, of which 2,700 cuttings and 22,300 grafts, 194,000 succirubras, and 80,000 officinalis, part of which will be kept for planting out in the west monsoon of 1883-4. The grafting of Ledgeriana and succirubra was carried on energetically. The experiments with the growing of grafts on succirubras in the open was attended with such continuous ill-success, that they were entirely discontinued. Of all the oculations, ferule and crown grafts, which have been made at different times in 1882 and 1883, not more than a tenth have succeeded. The experiments with the growing of grafts in propagating-houses under double glass again gave better results. The results would have been much more favorable if want of growing-room had not proved a hindrance. Of the five propagating-houses at Tjinjiroean two have had to be entirely demolished, and a third is gradually beginning to get past the useful stage. All available energy is being directed to the erection of new buildings for artificial propagation, but the want of skilled carpenters, who are needed so much for other operations also, is the cause of the building of propagating-houses not progressing as rapidly as could be desired. Grafting was confined for the most part to the propagating of Ledgeriana plants with more than 10 per cent quinine. The grafts were specially taken from the well-known mother tree No. 23, which shows 11·01 per cent of that alkaloid in its bark, and from which, moreover, such rich descendants were obtained. From the mother tree No. 38, also, which, although it does not show such a high yield of quinine (8·82 per cent), yet gives at least equally valuable descendants, a good number of grafts were obtained. The blossoms of both trees are peculiarly suited for reciprocal fertilization, the style of the first being long and that of the other short, and the endeavour is to be made to form only small plantations of each tree, in order to promote mutual legitimate fertilization. The artificial propagation of the richest plants raised from seed of the mother trees Nos. 23 and 38 was at the same time vigorously carried on. Among these were found some which at four years old showed a yield of 11-12½ per cent quinine from the bark, and which it will be advisable therefore to propagate on a large scale. The young trees however yielded no satisfactory grafts. The grafts of these trees standing in the open were encouraged by every possible means, such as manuring and thorough working of the soil, to make a vigorous growth, and should in their turn produce within a short period (in any case during the course of 1884) a considerable number of grafts. Finally, a hybrid obtained from seed of the Ledgeriana mother tree No. 23 was chosen for artificial propagation. This hybrid, corresponding in vigor of growth with a *C. succirubra*, but exactly like a rich Ledgeriana in composition of bark,—viz., with 10·3 per cent quinine and no quinidine and cinchonidine,—is, from its vigorous growth and its richness in alkaloid, of all known varieties and forms the most profitable for cultivation. Besides the advantages mentioned, which may be expected from a propagation of the hybrid, it can appropriate to itself the privilege of being alone used for the planting of old fields or uprooted plants, where the Ledgeriana type at first grows but slowly. For the production of seed the hybrid alone will probably not be used, and therefore it will not be mixed with the Ledger type grafts at Tirtasari. At Tjinjiroean there are about 200 grafts of this hybrid in the open, and during 1884 the extension of this valuable cinchona will be carried out as vigorously as possible. With the exception of the houses for artificial propagation at Tjinjiroean and of a small propagating-house at Nagrak, all such buildings on the other estates have been broken up. For the propagation of seed-plants they appear, in view of an abundant supply of seed, to be no more needed. Sowing in covered beds gave on the whole very good results. For the use of the southern estates nurseries were formed almost solely on Tjinjiroean. The other estate

were supplied as they needed with the plants obtained from the nursery-beds at that place. In the method of propagating important alterations were made. The largest plants are successively removed from the seed beds and placed in hardening-beds with a thick covering at equal distances of 2 Rhenish inches. If they are so far developed as to hinder each other in their growth, they are put into nursery beds of light materials at equal distances of 5 Rhenish inches, where they remain until they are fit for planting out. This method appears also to be much less expensive than that which was formerly most commonly followed. It is thus of the greatest consequence that only vigorous plants should be collected for transplanting to both the hardening-beds and the nursery beds. This is of so much importance, as the taking of too young, not sufficiently developed plants may very likely delay the propagating period 6 to 12 months The propagation of plants was carried on vigorously on all the estates, though not everywhere with equally good results. During 1883 a beginning had been made with the uprooting on a large scale of the inferior varieties of cinchona, and this will be continued with still greater vigor, as soon as a sufficient supply of plants of superior quality is available to plant up as quickly as possible the lands on which uprooting has been and is to be carried out. The crop of Ledgeriana seed of original trees was not large, and the numerous demands could therefore be only partially met. Large quantities of typical Ledgeriana descendants were, however, supplied free during the first half of 1883. The free distribution ceased in consequence of Government order No. 23 of 28th June 1883, to the effect that all Ledgeriana, succirubra and officinalis seed obtained from the Government cinchona estates and not required by them should be sold to the highest public bidder. The first sale was held on 4th August. Very high prices were paid for seed of original Ledgerianas. Some lots fetched *f*20 and more per gram, whilst for seed of typical descendants also fairly high prices—up to *f*5 per gram—were paid. A second sale gave much lower results. In consequence of combinations of private planters the greater part of the Ledgeriana seed fetched a relatively low price. The same seed which at the former sale realized *f*20 per gram went for a maximum of *f*2·50 per gram, while some lots fetched only *f*1 per gram. The fixing of upset prices was therefore recommended. The Government fixed these at, for seed of original Ledgerianas, *f*2·50; for seed of typical Ledgeriana descendants, *f*1; and for succirubra, *f*0·20 and *f*0·05 per gram. It must be confessed, that prices such as those obtained at the first sale would in the end impose a heavy tax on private industry, which is, in the public interest, not desirable. The prices have therefore been so fixed, as, while not discouraging the private culture of cinchona, to nevertheless guarantee a fairly profitable return to the Government. At a third sale, held on 29th Dec., the seed offered for sale was bought at the upset prices fixed by Government. In order to enable private growers to obtain seed of particular trees, at the beginning of March 2,000 Ledgeriana grafts of high yield were sold by public auction: 1,350 found buyers at the upset price fixed by the Government of *f*10. At the request of several planters, 650 more Ledgeriana grafts were sold at the beginning of November. Of these, 300 were sold at the abovementioned upset prices. The net result of the sales of grafts was *f*16,500, that of seeds *f*20,525·25. So far as is known, both grafts and seed were purchased solely for the extension of the cinchona culture in Java. A portion of the plants raised from the seed received from Hr. Schuhkraft in 1881 were planted out at the end of the year. The plants grown from the seed under the names of Cacola, Zamba-Merada, Durazmillo and Calisaya of Inquisivi appear, although the want of blossoms prevents any decided opinion, to belong to very inferior varieties. Those grown under the names of fine and finest Calisaya of Mapiri seem as if they must be referred to *C. Ledgeriana var. quinidinifera* and *C. Ledgeriana var. cinchonidinifera*, just as were the plants which were received in 1872 from Hr. Schuhkraft. It will be only by the blossom and the chemical analyses that a positive judgment can be given on the value of the newly raised plants. A more positive judgment can also only be given later on regarding the plants raised from seed referred to in last year's report. During the year, through the intervention of the Minister of the Colonies, a supply of seed of *Cinchona Verde* (*C. Calisaya oblongifolia*) was obtained. From this about 5,000 plants were got, which will be ready to put out in the wet monsoon of 1884-5. Nothing can yet be said with certainty as to the value and variety of these plants. From the seed received of late years from South America and elsewhere, only a small quantity of plants were put out. The results obtained from new kinds and varieties were on the whole disappointing. So far as a judgment can be passed, the new kinds are exceedingly like the worst varieties raised from the seed received from Mr. Ledger. Planting on a large scale of new kinds would probably lead to disappointment, without serving science in the least. The demands of forest conservators for succirubra seeds were regularly met. Renovation of the soil of old abandoned coffee gardens by the planting-up of *C. succirubra* was tried at some distance from the Tirtasari estate, which experiment will be tried on a somewhat larger scale in the wet monsoon of 1884-5.

3. *Extension and Upkeep.*—New land was not opened for the planting of cinchonas. Moreover this appeared needless, as the fields where inferior varieties, such as *C. Calisaya* and *C. Josephiana*, have been rooted out are perfectly suited for the planting of *C. Ledgeriana* and *C. succirubra*. Excluded from this is a small opening at Tirtasari, where a couple of bouws of jungle were felled and prepared for planting with Ledgeriana grafts. The greatest care was given to the upkeep of the existing plantations. The formation of deep trenches gave such good results in former years, that it was carried on as vigorously as possible. At Nagrak all the plantations were provided with trenches; on the other estates this work was confined to the Ledgeriana and officinalis plantations. The results of the deep trenching of the gardens was so favourable, that even plantations of inferior varieties at Nagrak, which would have been rooted out during 1884, were subjected to a like thorough working of the soil. The end had in view was not only the production of more bark, but also the gathering of bark of better assortments, of the greatest importance for the so-called druggists' bark. It is well-known that vigorously-growing trees also yield in proportion more quills than sickly and less vigorously-growing individuals, so that the bark can be more easily gathered loose and better in all forms. On the setting in of the wet monsoon the good results of the thorough working of the soil carried out in the dry monsoon were speedily visible, and a vigorous growth is to be noticed everywhere in the deeply dug gardens. The measurements of Ledgerianas, begun in 1879, were again carried out in the same month of 1883. In the Ledgeriana plantation at Tjibeureum the mean height of the six year old plants was now 3·64 meters, the stem circumference 0·24 meter. The maximum height was 4·3 meters, the max. stem circumference 0·44 meter. At Tirtasari the measurements of four year old grafts and cuttings gave respectively a mean height of 2·40 and 1·97 m., a mean stem circumference of 0·22 and 0·17 m., whilst the max. height and stem circumference were 4·03 and 2·50, 0·29 and 0·22 m. In consequence of the ravages of *Helopeltis* at Tirtasari the growth of the trees was seriously retarded, and therefore the measurements did not give the results which should have been looked for in the case of a normal growth. Among the unaffected trees outside the plantation chosen for measurement there were many stems of four years old which had reached a height of more than 5 meters. Considerable damage was caused during 1883 also by *Helopeltis Antonii*. The plantation of grafts and cuttings at Tirtasari especially had to suffer severe attacks. Strict orders were given to continue the pursuit of the insect unceasingly. By the end of the year the plants had completely recovered, only slight signs of sickness being noticed sporadically, and only at Rioeng-goenoeng were a few affected trees to be found in the Ledgeriana plantations. As a result of the stringently continued pursuit of the insect, it may with confidence be hoped that any considerable damage caused by the *Helopeltis* is a thing of the past. At Lembang considerable damage was caused to the Josephiana plants by caterpillars. Whole plantations were in a short space of time eaten entirely bare. In this case also the catching of the insect appeared to be the only method of cure. It was not always easy to reach the caterpillars in the already pretty high trees, and the catching was

therefore not carried out so speedily as could be wished. Although the trees have to a large extent recovered from the injury done, yet the loss is very considerable. The gardens which were intended to be uprooted and replanted with succirubra gave, on account of the difficulty in loosening the bark, caused by the disturbance in their growth, a disproportionately large quantity of broken quill and dust. The value of the product, which in the case of pharmaceutical barks is largely fixed by the appearance, is therefore considerably less.

4. *Harvesting of Bark.*—The crop of 1883 amounted to 208,370 kilograms, of which 207,170 kilos were taken for sale in the Netherlands and 1,200 kilos for the military medical service in [Netherlands] India. On most of the estates bark was gathered during the whole year; only during continuous wet weather gathering was stopped for some days, on account of abundance of bark. At Nagrak the existing drying oven appeared to render good service, and in spite of the long-continued drought this building was of very great use. During the year a second drying oven of larger dimensions was completed, and the building of a third has been commenced. The three ovens will be used continuously during a wet east monsoon, and even in favourable weather may render continual service, as the intention is to gather large quantities of bark of inferior varieties during 1884. At Tjinjiroean also a drying oven was finished, which was set to work at the commencement of the wet monsoon. At Rioeng-goenoeng and Tjibeureum buildings for the artificial drying of the bark will be erected during 1884. At Nagrak a plantation of 13 bouws of *C. Calisaya* was entirely rooted out. The trees began to get sickly in parts and to die off successively, which rendered a speedy harvesting needful. At Lembang also a plantation of 11 bouws of *C. Josephiana* was rooted out and prepared for replanting with succirubra. On the other estates also some smaller plantations of *C. Josephiana* and *C. Calisaya* were uprooted. The harvest was otherwise chiefly confined to the thinning out of old gardens, to the opening out of Ledgeriana and succirubra plantations, the purifying of the young Ledger plantations by the removal of hybrids, and the shaving of the old original Ledgerianas. The harvested bark of these trees was now three years old, an age when the quinine yield exceeds that of the original bark. Some trees which in former years were too small for the operation were for the first time subjected to it. The trees were not covered, but were also only shaved over the half of their circumference. The results showed that the trees bear the operation without suffering. Young Ledgeriana gardens, plantations of seedlings, have not hitherto been shaved, as it was not considered advisable to check these in their early growth. During 1884 a commencement can be made with the shaving of the 6 to 7 year old trees. As the shaving of trees to any considerable height from the ground, especially on very steep places, is attended with great difficulties, an experiment was tried with the cutting off of the top at a height of 12 feet above the ground. The experiment was tried with an officinalis plantation at Nagrak, and will be carried out on a large scale during 1884 on Ledgeriana plantations as well. Experiments must decide as to the manner of topping, the age at which it should take place, as well as the height above ground at which the trees should be topped. The product of the harvest of 1882 was sold by public auction at Amsterdam on 13th July 1883. The following prices per half kilogram were obtained:—

	Highest	Lowest	Mean.
C. succirubra ...	*f*1·73	*f*0·43	*f*1·33⁵
C. Calisaya Javanica ...	„ 1·46	„ 0·40	„ 0·97⁵
C. Calisaya Schuhkraft...	„ 1·60	„ 0·35	„ 0·94
C. Calisaya Anglica ...	„ 1·30	„ 0·40	„ 0·82⁵
C. Ledgeriana ...	„ 5·55	„ 0·74	„ 2·06⁵
C. Hasskarliana ...	„ 2·21	„ 0·76	„ 1·41⁵
C. officinalis ...	„ 2·65	„ 1·05	„ 1·84⁵
C. lancifolia ...	„ 1·48	„ 0·66	„ 1·10

The mean price of the whole parcel was *f*1·44 per half kilogram. The whole crop of 1882 realized *f*336,433·63 gross, *f*303,031·11 net. The dispatch of the product to Tjikao did not meet with the slightest hindrance. In former years difficulties were continually experienced, on account of the cattle disease then prevalent, but since the use of horses in place of buffaloes as beasts of draft has become more common, not only has the dispatch been speedier but, besides, the cost of transport has twice been reduced 10 per cent, thereby causing a great saving in expense.

5. *Staff: Expenses.*—At the beginning of March the Director of the Government Cinchona Enterprize was granted two years' leave to Europe on account of ill-health. The Assistant Director, R. van Romunde, was appointed in his place. The vacancy consequent was filled up by the appointment of Hr. A. A. Maas-Geesteranus as acting Assistant Director. The second class overseer, J. Zijmers, was dismissed from his office. The acting third class overseer was, after being first definitely appointed third class overseer, raised during 1883 to second class overseer, while C. Crietée was made third class overseer. The fixed native staff consisted on 31st December of 1 carpenter, 1 packing-house mandoer (also postman), 19 mandoers and 313 boedjangs. The supply of labor was nearly the whole year very large. In spite of the great demand for labor on the private estates, a sufficient supply of coolies was always to be had, which is principally due to the small coffee crop and the long-continued east monsoon, which is not favorable for the production of second crops. But other causes also must have excercised an influence on the large number of laborers. Fixed boedjangs were always to be had, if only work could be given to the women and children, which was done so far as practicable, by utilizing them for the upkeep of the plantations, harvesting, and the catching of *Helopeltis*. In the drying and sorting of bark and in the nurseries also the women did good service. Although it is an accepted rule, that the fixed staff shall be paid their wages only at the end of the month, no difficulties were placed in the way of discharge when request was made therefor. Day laborers were, as soon as they desired it, paid and discharged. And the conviction becoming stronger and stronger, that no difficulties could arise from free departure, it is felt that the repeal of Art. 2 No. 27 of the police penal regulations for natives will exercise a good influence on the supply of labor. The cost of the enterprise amounted to:—

Salaries of the European staff ...	*f*27,675·00
Stationery	350·00
Travelling and halting expenses ...	2,526·60
Wages of the native staff, construction and repair of propagating-houses, purchase and repair of tools, &c...	77,047·74
Total...	*f*107,599·34

being *f*33,138·34 more than was estimated in the budget for 1883. The much higher expenditure was caused by the harvest being far above expectations, the erection of buildings, and the more general adoption of a thorough system of cultivation, the results of which will be felt in future years in higher production. How far the additional expense incurred in cultivation is justified, may be seen from the following statement:—

Year.	Production in kilos.	Expense including transport to Tjikao.	Average per kilo.
1881...	82,697·5	*f* 74,590·75	*f* 0·90
1882...	126,595·0	„ 79,910·44⁵	„ 0·63⁵
1883...	208,370·0	„ 104,238·34	„ 0·50

The increased expenditure on cultivation over that estimated for in the budget of 1883 was largely recouped by the returns from the sales of seed and grafts.

6. *Distribution of Cinchona.*—There was no end to the applications for land for cinchona culture, especially in the Residency of the Preanger Regencies. Thousands upon thousands of bouws were taken up for the cultivation of cinchona. The difficulties of obtaining the necessary capital for carrying on, however, became greater and greater, so that the culture of cinchona did not increase to such an extent as would have been the case with a free supply of capital. Banks and commercial establishments appear unwilling to supply money for the growth of cinchona. Nothing more has been learnt of any desire among the natives to plant cinchona. Since cinchona has been planted everywhere by private persons, the experimental plantations in the various Residencies have lost their value. The profits to be got from the culture are not appreciated by the natives.

7. *Information regarding the Varieties of Cinchona Planted in Java.*—The hybrids planted out at Tjinjiroean continue to grow vigorously. Those produced by the crossing of *C. Josephiana* and *C. micrantha* commenced to blossom freely here and there. The blossom, like the habit, holds a mean between the two varieties from which they spring. Special attention was paid to the hybrid resulting from the fertilization of *C. Ledgeriana* with *C. succirubra*. As there are found among the blossoming specimens of these now some approximating in form of blossom to succirubra, then others to Ledgeriana, chemical analysis must decide the question whether the blossom is a satisfactory indication of a tree rich or poor in quiuine. The plants of *C. Trianæ* continue to grow equally well at all heights.

8. *Chemical Analyses.*—In place of Hr. Bernelot Moens, Hr. A. A. Maas-Geesteranus was appointed Assistant Director for the analysing of cinchona barks. The analyses made by him were chiefly specimens of the harvest. Conformable with an agreement with the retiring Director of the Cinchona Enterprize, the analyses of the barks brought to sale were performed by him, while he also undertook those made in the interests of the culture. The acting Assistant Director was thus relieved from performing chemical analyses, and from March 1884 he will be occupied with cultural operations solely. The results obtained by Hr. Bernelot Moens will, so far as possible, be given in the trimensual reports on the cinchona enterprize.

Bandoeng, 7th March 1884.

Director, Govt. Cinchona Enterprise.

Bandoeng, 7th March 1884.

CEYLON PRODUCTION OF TEA.

FROM AN INDIAN CRITIC'S POINT OF VIEW.

The question of tea planting and how it will pay in Ceylon is one which we hear discussed now-a-days pretty frequently. It is almost impossible to give any certain data on the subject, as there are no public registered companies quoted on exchange, nor do we in any way get reliable information. On one side we hear that as much as ten maunds per acre have been given by old lands that have borne coffee for many years, and we must say that we have to swallow this with a gulp, ere we can believe. Nowhere can our best and most experienced planters turn out anything like this from the best virgin soils put under tea in Assam, and it is not much wonder if most of the Assam planters are sceptical with regard to the yields as reported in Ceylon. It is not likely that the Ceylon planter can teach his elder brother anything with regard to tea, which is to the former an entirely new departure, for is not the coffee berry production the exact obverse to tea leaf production? At one time tea was supposed only to grow on teelah lands, but now that fallacy has been exploded, and it is but rare now a-days to hear of any extensions on such lands. So far as we are aware, coffee was in former years principally cultivated on pretty steep slopes, if not actually teelah and it would be strange if, with such a short distance as it is from India to Ceylon, the nutritive powers of that island should be, we may say, doubled, or rather more so. We may be accused after these statements of saying that Ceylon tea plantations do not pay, but we, by no means, go so far as this. We could mention the names of many concerns giving a yield of five maunds per acre, which have declared 40 per cent dividends; double this, and in less than two years the original outlay is more than realized, and every planter in Ceylon should have been in a position to retire long ago. In Ceylon, it must be borne in mind, in making any calculations, that the most expensive item is on the same footing as in Assam: we refer to labour. We imagine that in many instances the coolie costs the Ceylon planter quite as much as his Assam brother, and although in many instances the Ceylon planter does not house his coolie, he pays so much higher a rate for the same result, that this factor can be eliminated as not bearing on the question much, of how the tea industry pays better in Ceylon than in Assam. Perhaps the most reliable statistics we have yet seen on this subject is from the pen of Mr. J. Ferguson of the *Ceylon Observer*, and written to the London *Times*. In this article Mr. Ferguson gives some statistics with regard to planting industries generally in Ceylon, and with regard to tea he says:—"The current season will probably show an export in excess of two million pounds, and when the 35,000 acres of tea now planted are in full bearing in 1887-88, the season's shipment ought to be equal to ten million pounds. Eventually, it is estimated Ceylon should have 150,000 acres under tea, and an annual export of 60 million pounds and upwards. It depends on home capitalists very much how soon the result may be realized." We are not inclined by any means to take a pessimist view with regard to Ceylon tea, and we hope any Ceylon reader may not imagine so; but it is strange that this acreage almost coincides with the acreage of the Cachar districts in the Assam province; and so far as it is possible to divide the figures of outturn and that of Sylhet, the yield of Cachar is very much higher than that of Ceylon is expected to be, and if this is to be the case, it will be a case of *peccavi* with many an investor. Our own ideas on the subject are that tea can be produced in Ceylon at about the same rate as in Assam or Darjeeling, and no cheaper, and therefore tea profits must entirely be dependent upon whether Ceylon planters can turn out a much larger yield per acre than their Assam brethren.

Doubtless there may be circumstances attending Ceylon yield of which we are ignorant, but we have heard of several astute Assam planters taking a turn down that way to look for investments, who were not so enamoured with the plan as to think it capable of doubling the outturn of the Assam districts. So far prices for Ceylon teas have been slightly better than for the run of Assam lines, although some individual concerns in the latter stand out in bold relief above any other, and it is, as it always has been, a matter more of what leaf has been plucked than how it has been manufactured. Given the condition that the same leaf was rigidly plucked all over the different districts, and we do not think that prices would vary so much as they do now. That there are some planters more particular in little details we doubt not, but there are some well defined broad lines with regard to manufacture which all planters recognize and follow with but little variation, and this slight variation could not affect the general good result which they are aware follow certain lines. In conclusion, we believe that Ceylon teas will fall to the level of Indian, as is being already evinced in the London markets; at the same time, we believe that if the same economy is practised as is the case with regard to Indian, we see no reason why Ceylon tea planting should not take its place as a recognized industry, even although there may be a partial falling at the beginning, and a passing through the fiery furnace which Indian tea has long ago passed. —*Indigo and Tea Planters' Gazette.*

CONVERTING BONES INTO MANURE.

A correspondent, who is evidently adopting the wise system of combining the keeping of a due proportion of stock with his tillage operations, writes to say that he has accumulated a considerable quantity of bones on the farm, and asks for information as to the best way of converting them most effectively into manure; also, as to what crops and under what circumstances the bones may be most advantageously applied. As the information may be equally acceptable to many other of our readers, we have concluded that the answer may profitably be dealt with in this column. The putrefaction of bones may be accomplished by putting them into a heap (after they have been previously broken as small as possible), moistening them with water or liquid manure, and then covering them up with earth. In a few days the heap becomes warm owing to the heat produced by the chemical changes proceeding within the mass, and in the course of a few weeks the bones will be found to have lost their firmness of texture and become so soft that when applied to the land they quickly break up and mingle with the soil. It may be remarked that a heap of bone manure in putrefying loses considerably in weight, consequent upon the vapour and gases evolved during the decomposition of the organic matter. In order to reduce this loss to a minimum, it is advisable to use common salt, which, when powdered in occasional layers over the heaps, acts as a powerful antiseptic.

Another plan of promoting the solubility of bones is to place them in alternate layers with farmyard manure, when both are permitted to ferment together in a conical heap covered up with earth so as to prevent loss. Referring to this method of using bone dust, Dr. Stockhardt says:—"It is certainly most advantageous to employ bone dust like all subsidiary manures, not as an exclusive manure, but in combination with stable dung, whereby the latter is so strengthened that one load will accomplish as much as two without this addition. In a chemical point of view this method of proceeding claims to be designated as the most rational and preferable, since it leads to a mutual completion and equalisation of the ingredients, imparting to the mixture a higher value, and especially a more certain operation than either of these manuring agents would have separately." A plan used in America for dissolving small quantities of bones is to fill an old barrel with alternate layers of wood ashes and fresh bones broken in pieces with hammers, and slightly wetting from time to time with hot water. This is said to produce an excellent, easily soluble manure.

A more rapid, and, as it is held by the chemists, effective method of treating bones is to convert them into superphosphate of lime. It is claimed for this method that it is the most economical way of applying bones, the effects being more immediate owing to the fertilising elements of the bones being presented to the plants in a condition readily taken up by them. It is essentially the manure for the root crops and the top dressing of pastures, especially upon close retentive soils. It is prepared by pouring sulphuric or muriatic acid over the bones. The proportion of bones and acid to be employed are as follows:—1 ton of inch bones, ¼ ton of sulphuric acid, 60 gallons or ¼ ton of boiling water. The requisites recommended are a cistern of lead, or even of wood strongly made and bolted together, and a watering can of lead. A small quantity of the bones should be spread upon the bottom of the cistern, and the sulphuric acid gradually poured in from the leaden watering can, at the same time that a proportionate quantity of the water is added from another watering can. More bones should then be thrown in, then more acid and water; and in short the process should be managed so as to mix the bones, water and acid as uniformly as possible. The mixture should be allowed to stand for some days before it is employed, and it should then be mixed with some dry peat or soil in order to render it sufficiently dry for use. The mixture thus made may be preserved for any length of time before being used, so that it may be made at any time which may suit the other operations of the farm, all that is necessary being that it shall be kept under cover.

A substitute for the leaden cistern or wooden box referred to may be obtained by puddling a clay floor, upon which, after it has been allowed to dry, the laying on of the bones can take place, and the mixture of the acid and water, similar to what has already been described. The sides of the pile in this case must be made by building ashes round the bones and trampling them well as the formation of the heap proceeds.

With respect to the effect bones have upon the soil, they exercise a varying influence according as they are applied—in their dry and roughly broken state; their boiled, reduced and putrefied condition, or when prepared as superphosphate of lime. Even in the first-mentioned state the wonderful effect of bones was demonstrated when, upon the first discovery of their manurial value in England, they gave the worn-out pastures of Cheshire a complete renewal of all their early fertility. This is easily explained when we find it proved by chemical analysis that there is about 1 lb. of phosphate of lime in every 25 or 30 gallons of milk, and that the yearly demand made upon the resources of the soil by one cow is equal to about 80 or 90 lb. of bone. Touching the action of bone manure in the second of the conditions referred to, an eminent chemist says:—"In the fresh bone dust the nitrogen exists mainly in the form of cartilaginous substances, and the phosphates in a nearly insoluble state; it is therefore only when the process of decomposition in the soil has converted the nitrogen into ammonia and other available forms of combination, and has rendered the phosphates more easily soluble in water, that the manure can minister to the requirements of growing crops. In fermented or rotten bone dust, on the other hand, the chemical changes referred to have already taken place, and the constituents are to a considerable extent capable of being immediately utilised by plants." By converting bones into the third condition referred to, viz., superphosphate of lime, however, the quickening action of their fertilising elements is so increased, especially in their application to root crops, that Scott Burn quotes an illustrative case in his own experience of a farmer who proved one bushel of superphosphate made by dissolving the bones with a third of their weight of sulphuric acid to be equal to four bushels of simple bone dust.

The question as to what crops and under what circumstances bones should be applied must be decided by the agriculturist according to rules affected by his surrounding circumstances. Assuming it as agreed that bones should be applied mainly to the lime and potash variety of plants, commonly alluded to as the "green crops," and which include the grasses, peas, beans and the mangold, potato, onion and other roots, the form in which they should be applied will be determined in a general way by the nature of the soil. In open, non-retentive soils, from which the more soluble manures are liable to be washed by the rains,

bones in their least active condition will be found most suitable. Where, however, the soil is close of texture and retentive in its nature, together with a climate giving a paucity rather than an excess of moisture, a maximum quickness of action such as is produced by the superphosphate process is desirable. Although mainly used for the green crops, it must not be assumed that bones are not of value as applied to the silica crops. Considering that cereal crops, especially wheat, remove from the soil a considerable proportion of phosphates, it was regarded at one time as unaccountable that the application of bones to such crops was not followed by any adequate result. The mistake, however, was in applying the roughly broken unfermented bones, which are altogether too slow of action for this class of crops. For these the active superphosphate must be used, and even then it requires putting in with a previous crop, or at latest when the seed is sown, or just after, in order that it may receive the quickening action of the autumn rains. In England, with its moist climate, a favourite top dressing of the wheat crop in the spring consists of a mixture of 2 cwt. of superphosphate and 1 cwt. of nitrate of soda per acre; but in this colony a better result is obtained by the superphosphate being put in with the crop, or just after sowing, and applying the nitrate mixed with its own weight of salt as a top dressing in spring, when the process of vegetation is most active.—Melbourne *Leader*.

COFFEE, CINCHONA AND TEA IN THE HAPUTALE DIVISION OF UVA, CEYLON.

A visit to any of the planting districts now-a-days, after a long absence, supplies much food for reflection, and a trip through what always was, and still is, the premier district is no exception to the rule. The change in Haputale that has taken place during the last four or five years is marked and somewhat saddening. It is not only that there are new faces as well as new products, but everything is different—the crops, the coffee itself, the planters, their prospects, their habits and their conversation. Perhaps the appearance of the coffee has changed least, but on the second-rate estate there has been a perceptible retrogression, and even the best properties are beginning outwardly to show signs of sliding down the hill which the bulk of Ceylon estates have been descending for a long time. There are still sheets of fine coffee to be seen in the district on which leaf-disease comes and goes with apparently little effect, but the crops are not there. It is true next year's prospects are more favorable that last year; and they had need be. But, though a small crop will generally be succeeded by a large one as of yore, the rally is not quite up to the last one, and the maximum outturn of alternate years is receding like the waves of an ebbing tide. How much diminished cultivation may have to do with this it is difficult to say, but, with coffee at present prices, he is a speculative man who goes in for high cultivation. Haputale never indulged in much artificial manuring; it was too costly, and the amount of coffee manured in the palmy days of the district formed but a small portion of the whole acreage. There must be thousands of acres in the district that have never seen an ounce of manure, bulky or otherwise, since they were opened, and never will do so now, for, even if the railway staggers along to the Pass, and does not founder at Nanuoya, what is the use of manuring with coffee at sixty-five shillings?

Indeed, I heard the question discussed recently whether, at the time, it paid to pick the autumn crop on the trees? This may seem a paradox, but you see the outturn of light coffee after the drought has been terrible, ranging from 30 to 60 per cent, and many estates' *palam* has turned out parchment and light in equal portions with strict impartiality. Such being the case, and the daily picking perhaps half a box, does it pay to pick? Is it profitable to pick less than a box with present prices and present outturn?—that is the question that I heard seriously debated. And if the condition on which it pays to gather crop in Haputale have undergone a change, there has also been a revolution in pruning. The time was when the term "Kandy-side pruning" offended the nostrils of the bulk of Haputale planters, and sundry were the jokes cut at the expense of the system as carried on outside favored Uva. When Kandy-side coolies were taken on in Haputale in the good old days, they had to be watched closely in the pruning field to prevent them turning the trees into cart-wheels and otherwise hacking the valuable trees, laden with crop. "Heavy pruning is all very well for those Kandy-side places," would say the planter of the old school, with slight contempt, "for they won't give crop without it," and the gloomiest forebodings were uttered as to the ultimate fate of those Haputale places that went in for "Kandy-side *mahdri*." This, however, is changed, and "Kandy side" now sets an example in moderation and forbearance. I heard, indeed, that a visiting agent from the neighborhood of Kandy was recently horrified at the sight of a Haputale field, where the littered ground showed that the pruners had had a regular field-day, though many of the places that used to prune heavily have given it up.

With regard to cinchona, when one remembers the prospects of about three years ago, the presents state of affairs is disappointing. When the craze for cinchona set in about six years ago, the outlook for the quinine tree in Haputale was promising in the extreme. Though the amount put out in the coffee was not so large—the necessity not being so urgent—as in shuck districts, small clearings, both jungle and patana, were planted up, and for a time prospered exceedingly. It looked indeed as if Haputale, which had grown coffee so well, was going to show other districts how to cultivate cinchona. This idea is now all over, for Haputale has shared the fate of too many other localities, in spite of its splendid climate. The death-rate on many places has been heavy, while in the clearings whole sheets of young cinchonas have gone out of existence. Not regularly though, and seemingly after no fixed rule, for the mortality has been on jungle and patana clearings alike, while there are still small fields of both kinds flourishing, in a more or less favorable manner. The causes which have led to the setting-in of canker are as much a mystery as ever, so that no one can tell how long his present cinchonas will last. This being so, it is not difficult to understand why planters should be planting up their cinchona with tea, and even uprooting cinchona to make room for the coming product.

For Haputale is not going to be behindhand in the new cultivation. Nurseries are springing up, and this monsoon now at hand will see many acres planted out. Already lining and holing are going on, and the former on land already thickly planted with coffee and cinchona is no easy task. With these three products all growing side by side it will be a veritable case of "survival of the fittest." Whether tea will prosper remains to be seen, but it will not be for want of trying, as it is being planted out in every kind of soil and situation. Quartz ridges and sterile patanas will be experimented on along with more promising fields, and, if tea will grow on some of the localities now being planted, it will grow anywhere in Ceylon. The acreage put out this year will not be small, for, though most of the clearings will only be from 10 to 20 acres, one estate, Kalupahani, is going in for 120 acres this year. The first time I saw Kalupahani was in 1875, and there were not many patches in the fine sheet of dark coffee then. The white streak, where the coffee had gone out on either side of a ravine, and here and there a small patch in the centre of a plot, were all that then indicated the presence of the mysterious disease which has seized hold of this once magnificent property. The white rings have grown and grown till they promised at one time to absorb the whole estate. To cover up the nakedness of the land the ubiquitous *succirubra* was planted largely, but the land was flat, and not particularly suitable, and today the cover is poor in the extreme. I was pointed out the premier patch of tea in the district on the Haputale side of the Kalupahani bungalow. Though planted wide apart, the trees make a fine show, and are evidently fine specimens of their kind, hardy, strong, and vigorous. The bushes are said to flush extremely well, but the smallness of the patch prevents anything being done with it. The superintendent having received instructions to plant up 120 acres, has selected that portion of the estate nearest Haldummulle, from Webster's culvert onwards, and the whole of this portion of the estate is lined, and new being holed for tea. This monsoon will see the whole 120 acres under that product.

A noticeable feature in the new order of things though is the burning-out of 20 acres of high coffee on one of the crack estates above the Pass to make way for tea!! Talking about burning out, the question as to the effect

of Haputale droughts on tea will soon be settled. What a dry season in Haputale is like the past month or two has shown, and if coffee has suffered so much, what is likely to happen to tea-flushing? Not only is the rainfall in the district light, but it is not well distributed, and of late there has not been enough water for curing purposes on estates generally well off, and more than one estate has had to unship one of its cylinders to get the pulper to work at all, so scarce is water.

After tea has been generally introduced, it will be worth noticing how the older coffee planters take to tea-making. Not very kindly, I fancy. The introduction of cinchona led to some jealousy and heart-burning, and it certainly was hard that old planters should have to learn how to grow the new product from young men who had been but a few years in the island. And a similar feeling will probably be engendered in many cases in the matter of tea cultivation. But necessity does wonders, and Ceylon planters have never shown themselves slow at adapting themselves to circumstances. Already tea is commonly the subject of conversation in Uva bungalows, and planters are always willing to give or acquire information as to its cultivation. One planter I heard ask rather anxiously if it was true that you had to get up in the middle of the night to attend to curing operations, and on being reassured on the point he smoothed his brow and muttered something about being a sound sleeper. It is seldom that coffee or cinchona is talked about now, except when a further drop in the market gives rise to temporary excitement. Nor is the coming "bumper crop" alluded to as a rule, though one can't help remembering the time when it gleamed ahead of everyone like a will o' the wisp.

It is not now considered certain that "Haputale will never grow tea," as was at one time the case, the only suspicion on this point being reserved for some of the drier portions of the district. I also saw preparations for tea being made on Ampitiakande on the Koslande side of the Gap in by no means promising land. In this connection it is worth noticing that in this district, as in many others, the first plunge into tea is being made on the most unpromising plots of the estates, bare ridges and patches of died-out coffee, and, in one case, on a patana clearing planted with cinchona. On the latter, the plants were about twelve months old, but not very big for their age. The suitability of the district for tea can hardly be gauged with any degree of impartiality by the result of these experiments. That such spots as the Kandapolla Valley and the Haldummulle side have a fairly good tea climate I am convinced, but any deficiency in this respect is more than made up for by the gloriously rich soil of most of the estates in the district. Old coffee land seems to be very much despised as a tea-producer by your worthy correspondents "Fez," "Spero Meliora," and others, but if they saw the soil on some estates up here, which have given crops of coffee for 30 years and more, those gentlemen would not so readily decry old coffee land for tea. Take such places as Blackwood and Wiharagalla, the upper part of Golconda and Kelburne, old Haputale, Roehampton and most of the Mecriabedde and Poonagalla Valley places; where will one find better soil for tea, or anything else, than is to be met with on those properties? Compared to it, some places that I wot of, giving their 400 lb., aye, and their 600 lb. made-tea per acre, cannot hold a candle. I have often heard my old P. D. assert that no soil in the island comes up to some to be met with on the old Hunasgiriya places, and subsequent inspection has satisfied me that he was not far out. Estates in that old district, where, in the past, so many tons of coffee have been produced, are now being planted up with tea, and, like estates in Haputale, when they are put under the coming product, should flourish exceedingly.

The cinchona craze has died out here as extensively as it has in most other localities. It was a disease from which we have all more or less suffered, and our disappointment is no less keen because it is borne silently. Looking up from Haldummulle one can see, high up on the ridge of hills above, the spot which was once considered to be so rich with its wealth of cinchonas—the Kalupahani Valley. A good glass would show field after field abandoned, with the roads and drains in prominent relief. I remember walking down through the valley in May, 1822, with one whose stake in it then was, perhaps, larger than that of any one else, and, though the inevitable "patches" were here and there discernible, the prospects for what was standing were considered good in the extreme. The soil was good, the lay of the land excellent for cinchona, being steep with fine drainage, and the land was opened carefully after the most approved methods. Looking back at the higher estates from those beneath, I thought what a splendid sight these estates would present in another couple of years. How the light shade of the succirubra and the deeper tinge of officinalis in magnificent sheets would set off the dark fringe of the forest above, topped with its everlasting white and fleecy crown of clouds! But how different the reality is! I believe Lentran and one or two other estates are being put into tea, and that hopes are entertained that it will be a great success; and I certainly don't see why it should not, for the rainfall is abundant and well distributed, whilst the soil is, as I have said before, exceedingly good. I forgot to remark upon the cinchona clearings of Roehampton, Kahagalla and Gonamatava, all of which contained far fewer vacancies and patches than I was prepared for. The trees have made a fair growth, and form in places a splendid cover. That portion of the "as-yet-untouched-patanas" on which these clearings stand appear to suit cinchona excellently. —Local "Times."

DRIED APRICOTS.—California fruit-growers have discovered that apricots bleached with sulphur fumes and then dried in the sun are superior to those that are dried in any other manner, or that are canned. They regard this fact of very great importance to the whole State. It enables every fruit culturist, however limited his means, and however small the product of his orchards, to dry his own fruit for market, and makes him independent of the canning factories. It is also stated that fruit can be prepared in the same manner more cheaply than in any other, that its weight is better preserved, and that it is of superior flavour.—*Journal of Horticulture.*

WASPS AND RED SPIDER.—Having had my attention recently attracted by the continual visits of wasps to a second early peach house, I have wondered what they were in pursuit of, as the fruits have been cleared for some time past. I have now come to the conclusion that they are in search of red spider. The trees in question have not been syringed since the fruit ripened, and yet they are as healthy as possible, which is not often the case under these conditions, as when left to themselves red spider is sure to appear. Although these trees have been so far neglected for several weeks, red spider is very scarce, and this I attribute to the visits of wasps. They crawl about on the upper and under sides of the leaves, apparently in search of these insects, or why should they continue to visit this house in such numbers when there are other houses adjoining with ripe fruit yet ungathered? I would like to know the opinion of some of your readers on this subject. No doubt there will be some that will pooh-pooh such an idea; but why should not wasps have a liking for the red spider as well as for flies, for they will demolish these ravenously when within their reach and other food is short.—S.—*Ibid.*

CHOU-CHOU PICKLE.—The recipe which I have proved to be most trustworthy, is as follows:—"Take 2 lb. of green tomatoes, bruise them, then add two or three medium-sized onions, sliced according to size, and six chillies; scatter salt over it, letting it stand fifteen hours, then strain away the moisture, and cover the remainder with good vinegar. Bake this in an oven for one hour, and then press the pulp into jars. Now take a dessert spoon each of mustard, pepper, mixed spice, half teaspoon each of sugar and cloves, a little cinnamon, and four chillies, adding sufficient vinegar to make this quite thin. Boil it and pour over contents of jars while boiling hot." Another good recipe under the heading "Tomatoes for Pies" may also be acceptable to some of my readers who may have a quantity of green fruit too backward to ripen. "Pick the tomatoes green; scald them and take off the skins. Put them into a preserving pan, and let them boil for half an hour. Cut them up, and put in 1 lb. of sugar to 3 lb. of tomatoes, and let them cook for half an hour longer. Season them with the juice and peel of lemon, and put them away in jars. These make very good pies in the winter, and resemble Gooseberries."—W. IGGULDEN.—*Ibid.*

TEA AND TERRACE CULTIVATION.

With reference to the statement made by a writer, by no means inclined to be over-sanguine, that the soil of Dimbula would grow tea for a century, it was remarked to us that the planters of Ceylon did not take proper care to preserve their soil by means of terraces. We adduced in reply the great difference between most of the soil of Ceylon and that of Assam and Darjiling, which so strongly impressed Mr. Owen, and which he so emphatically described in our columns. The deep alluvials of the valley of the Brahmaputra and the forest humus and schistose soil of Darjiling, as well as the volcanic soil of Java, are each light and easily washed away in proportion to their riches. Over a large portion of the mountain and hill slopes of Ceylon, the soil is, on the other hand, a stiff clay, through which the tea-plant easily forces its taproot and in which it flourishes. This soil, if scored with frequent drains and paths on easy gradients, will suffer the minimum of wash; for a certain amount of wash cannot possibly be avoided. Then in Ceylon we do not hoe the soil but stir it cautiously with forks. Our soil is a good tea soil, but not rich enough, as are those of Java and India, to support both tea and weeds, including the terrible *iluk* or *alang-alang*, which, both in India and Java, is allowed to grow so as to bind the outer edges of the terraces. In Java there is little difference in many places between surface soil and subsoil, and the same can be said of much of the soil of India. But, in Ceylon, terracing would result in bringing to the surface a subsoil which would require a year at least, perhaps several, of aeration to make it fertile. This fact and the prohibitory expense largely account for the absence of terracing on a large and systematic scale on Ceylon estates. Terracing, after the Indian fashion, involves the removal of every stone and stump and root, and those who, like the writer, have tried even a small experiment after this fashion know how entirely out of the question is the complete terracing of an estate of any size. Much was done in utilizing loose stones on estates, under the influence and at the advice of Mr. John Hughes, the chemist who came out at the instance of the Planters' Association to report on our soils and the best methods of combating the various enemies of coffee and altering the conditions adverse to the growth and crop-bearing of the plant. But we fancy that in none of the cases where such means were resorted to, was the benefit at all in proportion to the expenditure. We should be glad to be corrected if we are wrong, and to learn if terracing on an appreciable scale has been tried in Ceylon with reference to tea. We tried terraces for cinchonas in excellent looking soil, but unsuccessfully, although, curiously enough, there are no positions in which the fever plants flourish so well as in the subsoil below deep cuttings on roadsides. But such subsoil has been effectively operated on by the atmosphere and is enriched by washings from the roads. Were unlimited money available and could the planter delay planting until his upturned subsoil has been brought into proper condition for the reception of plants, no doubt the perfection of cultivation would be a system of trenches in which all the jungle cut down should be buried, except special trees required for timber purposes, the stones, except the large boulders, being used for lining and supporting the outside edges of terraces. The late Dr. C. Elliott, in papers entitled "Coffee Cultivation as it Was, Is, and Ought to Be," recommended such a system; but practical planters objected first to the prohibitory expense and second to the great danger of a whole hill-side being swept away in one of the rainstorms which occasionally occur in our mountain regions. It is difficult to combine an efficient system of drainage with terracing, for the terraces must slope inwards and not outwards; and with stagnant water on one side and hard soil on the other, the plant would not be in the most favourable circumstances for healthy growth and life. Such objections as these are quite familiar to Indian planters, one of whom stated, as the result of an experiment, that his plants on unterraced soil were at the end of the first year twice the size of those planted on the terraces, and that the disparity was equally apparent at the end of the second and third years. The balance of testimony in the *Tea Cyclopædia* is decidedly adverse to terracing, at any rate on the "teelahs" of Assam, Cachar and Sylhet. Those who voyaging up the Rhine have observed with admiration the carefully terraced vineyards on its banks, with similar culture in the South of France and in Switzerland, are naturally prejudiced in favour of a system which undoubtedly saves valuable soil. But the vast majority of the vineyards of Europe are small patches, kept in heart by the constant toil of their peasant owners; a vineyard of one hundred or two or several hundreds of acres being very exceptional indeed, But about 200 acres is the average of our estates in Ceylon, where coffee has been and where tea is to be. It is certainly regrettable that any of our soil should be lost by wash; but a certain annual loss is inevitable, and the true remedy is not a system of terracing, prohibitory in cost, but a liberal and scientific provision of drains and paths, equivalent in many respects to terraces, but superior to them in the facility they afford to the flow of superfluous rain-water off the surface of the soil into ravines and streams and rivers. The percentage of particles of soil which we cannot prevent from being carried away by exceptionally heavy rains, and which are deposited in the ocean, will yet be upheaved for the benefit of (let us hope) a grateful posterity, while on well-managed fully cultivated estates the upper subsoil is gradually fitted to take the place of what was the surface soil. When terracing is proposed to planters in Ceylon, it is their poverty mainly, no doubt, which forbids consent; but, as regards their will, they generally, we believe, would prefer (looking at the mechanical condition of most of their soil) being able to score their hillsides with a close system of drains and paths at a gradient of 1 in 30.

But it is not merely the soil over a large portion of the hill region of Ceylon which differs from that of India and Java in being more tenacious; the climate is also different. Except in the portion of the mountain zone directly facing the track of the south-west monsoon, excessive rainfall and destructive rainstorms are of rare occurrence. Over the vast proportion of the hill estates, the rainfall is moderate (from 70 to 140 inches) and well distributed over the twelve months. Occasional rainstorms of 5 to 10 inches in twenty-four hours we have to record, but the violence and destructiveness of such phenomena are as nothing compared to the effects of tremendous downpours in Darjiling and considerable portions of Assam (including Cachar and Sylhet) in the neighbourhood of the Khassia Hills, the most rainy reigon on the globe. In India, it is no uncommon experience that the vast mass of a rainfall ranging from 150 to 250 inches should be concentrated into the four or five months of the year commencing with June and ending with October. On the Naduvatam cinchona estate, Nilgiris, 102 inches of rain out of 195 for the whole year fell in the single month of July 1882. Half this quantity in a month on Templestowe estate, Ambagamuwa, is the heaviest fall in one month we can recall as recorded in Ceylon. We need scarcely remark that the more loamy and

loose a soil is and the less clayey and tenacious, the more is its liability to wash. Now most of the soil of India and Java is free loam, richer than that of Ceylon (which is, however, a very good tea soil), but more readily carried away by rainstorms. Mr. Hughes' verdict on the soils of Dimbula and the adjacent district was :—"Fairly characterized by most of the elements of fertility in good quantity excepting lime, but defective in its stiff mechanical condition." Tea does not demand a large proportion of lime, however, while it is more than tolerant of a large proportion of alumina and iron. Our stiff soil well suits the product which is now becoming our staple, and it far better resists the wasting effects of rainstorms than the richer but looser soils of India. And there is another consideration. Very steep features on mountain plantations can be bound by tea bushes planted at distances from or rather close to each other, which would never have answered for coffee. Such features can be planted at one foot apart in rows across the face of the precipitous places, with a space of two feet between the rows. Such planting will prevent both landslips and any material degree of wash. The perfection of tea planting we believe to be about 3′ or 3½′ by 4′ on moderate slopes, as close as we have indicated on steep faces, and hedges of closely planted tea bushes on both sides of all roads, paths and drains. With such a system (paths and drains being frequent), and careful forking, the amount of wash would be reduced to a minimum. Then as to shelter where wind is so strong as to be injurious, let it be noted that it has been proved that tea trees in Ceylon will grow to a height of 20 to 30 feet. Shelter belts of tea bushes might, therefore, be allowed to grow at proper distances across the fields, such belts yielding both shelter and seeds—or leaf, if it is deemed well to prune and trim them. With such a system of culture on tea estates, terracing can well be dispensed with.

A PLANTER'S LIFE AND GOSSIP.

ADAPTABILITY OF THE CEYLON PLANTER—NEW PRODUCTS—INVENTIONS—HOW TO PREVENT THIEVING—PROSPECTS OF CACAO—COFFEE BEING ROOTED OUT IN BADULLA TO BE REPLACED BY TEA—A COFFEE CROP IN THE DAYS OF OLD—PRUNING COFFEE WITH AN ALAVANGA—A DRASTIC CURE—RETURNING COLONISTS—AN ERST-WHILE COFFEE PLANTER IN A NEW SPHERE.

22nd October 1884.

It has been recognized as a distinguishing feature of the Ceylon planter, his ability to adapt himself to a changed environment. If an old product fails he sets about trying another, and, if there be any kind of promise in it at all, it is encouraged by a liberal mixture of brain to do better here than it has ever done elsewhere. We took to cacao, and the Ceylon marks quickly topped the market; we grew cinchona, and have driven the South American bark out of the field; we have planted tea, and, not only have the profits been great, but the outturn per acre have astonished ourselves, as well as the older race of Indian tea planters. If a new invention be wanted to save the cost of labour, to give a quicker dispatch, or a surer result, we are not content with the old and tried, but scheme and plan for something new. What a catalogue of Ceylon inventions one could detail! Scissors and bleaching machines for cardamoms, road tracers, and transplanters of all kinds, drying stores for bark and cacao, pulpers for coffee, tea-rolling machines, indiarubber tappers, *et hoc genus omne*. Even on such a simple tool as a weeding scraper, the amount of thought and ingenuity which has been expended in the last decade or so is marvellous. In Walker & Co.'s workshops in Kandy are samples of those they have from time to time manufactured from hints or drawings are duly preserved, and the array is a goodly one. Many of them are of course now practically useless and obsolete, still around each there is a history, and all tell of a purpose they have served.

Spite of this wealth of invention, I have yet to chronicle another. It is a new dodge, its purpose being to prevent thieving. Like many other great inventions, the discoverer stumbled on this one, and, although he might have set up a claim to honour for having evolved it from his own consciousness, without a snarling public being able to gainsay his right, yet he purposes taking up a humble position. Sir Isaac Newton was not ashamed to admit that he had learned much from the fall of an apple, so this new benefactor of the planting tribe takes his stand on a similar platform in the attitude of course of a lowly disciple, and says that that problem of problems, the outwitting of the thieving native, solved itself in his case when he erected a cheeta-trap. Many apples had fallen ere the historical one dropped from the bough at the feet of the great philosopher, which was the genesis of a train of thought leading to the discovery of a univeral law, and so with the cheeta-trap. Hundreds have been set up from time to time, but what problem have they ever solved before?

The effect is got in this way. You have a field open to the enemy, and into which he loves to raid. It is of necessity considerably removed from any habitation of man, lonely and outlying. Here you get up the needful footprints, lock up your dog for a few nights, warn your cattle-keepers, drop hints to your coolies, and set up the trap. When that has been done, you may withdraw your watchman, sleep comfortably, and for the rest of the season your soul may be at peace and your coffee safe. The discoverer of this invention has this year found his plan work so well on the estate on which he is resident, that when I saw him last he was then starting for another part of the country, where thieves do abound with the express intention when there of working up another cheeta-scare. He is prepared to stake his honour on the success of the dodge if carried out as it should be. No thieving native will enter a field of coffee in which, preliminaries having been duly attended to, a cheeta-trap has been erected. The clutches of the law he has often evaded, will run the gauntlet of them again and again if need be, but his courage evaporates, and his arts are nought when he is brought face to face with a rude trap, and has his mind filled with the horrors of a cheeta-scare.

Cacao is going to do well, if the promise of blossom be any indication. In Dumbara where during the drought there was much anxiety, and where even now the effects are to be seen in places where the soil is thin, and even below, the late rains have done much good. Some of the trees, which, seemed to have succumbed, have picked up, and the luxuriance of blossom is a sight to see. It is setting well also, and the promise of crop is better than it has been for a very long time.

As an example of the faith in tea, and, alas! also of the want of it in coffee, I have to record that one of the Badulla Companies is rooting out coffee on which there is estimated to be about 4 cwt. an acre set.

This may be wisdom or the reverse. It reminds me of an incident in the days of old, how, in the same district, a proprietor had such a glut of crop, that he closed his season and cleaned up his pulping-house while on the higher portions of his estate there still remained something like 5 cwt. an acre to pick. When remonstrated with, he said he had enough, and was content to let the balance go to waste!

Pruning coffee with an alavanga is a new idea. Still I was hearing of a man who is almost won over to

the belief that it is better than the knife. He was planting up one of his old fields with tea, and desirous of giving every chance to the new plant, sent in his coolies to smash down the branches of the coffee with the rough and ready alavanga. The work was done effectively, and now the maimed trees, which for some seasons back have refused to do ought else than hold their own, hide-bound and barren, are full of life, throwing out new wood in an amazing way and leading up to the conviction that for pruning old coffee the alavanga is likely to be the tool of the future.

Many of our old colonists who left us during the darkest days of our depression are returning again to Ceylon. They drop in one by one, and all have the same tale to tell, that of a hard struggle, in ungenial surroundings. What our old men have not turned their hands to, would be more difficult to say than to recount their trades. They have gone to every point of the compass, tested every new country from Manitoba to New Zealand, and it says much for this beautiful island, and the pleasant life the planter has now, that those who can return do so, and those who can't wish they could. As an example of the willingness and grit of our men, I may say, that, about eighteen months ago, I met, in one of the small towns of Southern California, one who in former days had here cultivated coffee. The bad times had driven him out, and when I saw him he was there employed to use his own expression "hossing an eating-house." Some remarks which passed between my companion and myself, and which he overheard, drew him to us, and during our short stay in the place, about half-an-hour or so, we had his company. The old guild feeling of the planter, added to the "hail fellow" sentiment of the great republic, made him quite at home, and after many enquiries he saw us on board our train, and bade us an affectionate adieu. It was a queer life he was leading, its most prominent advantages being that he had "the run of his teeth" sure, and the honour of being addressed as "jidge."

PEPPERCORN.

QUININE: FABBRICA LOMBARDA DI PRODOTTI CHIMICI:—MEETING OF CREDITORS.

(SPECIALLY REPORTED FOR "THE CHEMIST AND DRUGGIST.")

The meeting of the creditors in the bankruptcy of the Fabbrica Lombarda di Prodotti Chimici took place in Milan, on September 5th, at 12-5, in the Hall of the Tribunal of Commerce, in Via Clerici.

The meeting was presided over by Judge Biraghi, who opened the proceedings by inviting those present to inscribe themselves in the list of creditors. The creditors present or represented were fifty-four; most of them were represented by well-known Milanese barristers.

Professor Maglione, temporary curator (appointed by the tribunal of commerce to represent the creditors during the bankruptcy proceedings), then read a detailed report. Before summarizing it, it will be convenient to mention a report which was also presented by the Board of Directors of the manufactory.

The Board of Directors in their report state that, besides the duty of supplying to the creditors all available information, they intend to put forward their legitimate defences against all those who, both now and before, tried with violent language to burden the Board of Directors with a moral responsibility that none of them ever accepted or intended to accept. As to the legal responsibility—they leave it to be settled by those who are competent to do it.

They state that the rules of the Society have never been violated. According to rule 15 the Board of Directors must have an ordinary meeting once a month. It has always been held, besides several extraordinary meetings. According to Rule 20 the two managers have very large powers entrusted to them, with full authority to do and undo at their pleasure. In the extraordinary meeting held on May 15th, 1882, the Board of Directors rescinded the engagement with the manager, Alessandro Böhringer. This was to have effect on July 1st, 1881.

The first cause of the bankruptcy dates as far back as the year 1880. According to the advice of the manager, A. Böhringer, the capital was then increased, and the production of sulphate of quinine was brought up to 200 kilogrammes daily. It was aimed at dominating the markets of the world, and at checking the wild speculation which had seized and monopolized the trade in the raw material. In order to produce bark, the Society bought some lands in Columbia.

It was soon seen that the forces of the Society were unequal to the task, and it was resolved to limit the production. This happened in the measure of about one-third in the year 1882-83, though Signor A. Böhringer and the managers made very onerous contracts without the knowledge of the Board of Directors. It has also appeared that frauds have been committed. In the balance-sheet of June 30th, 1883, were entered 960 bales of quinine. ("bark."—ED. C. O.) which only arrived in the store during July: the average chemical analysis was elevated to 2·02 which figure was false by 35 per cent, the real average being only 1·28. As these figures were within normal limits it was impossible for the Board of Directors to perceive the alterations, which had been perpetrated by Signor A. Böhringer, with the silent concurrence of the administrative manager and one of the directors.

The report then explains at some length the reasons of the difference between the balance-sheet presented by the directors on June 30th 1884, and that compiled by Professor Maglione on August 14th.

It ends by recording the opinion of the directors that the manager Alessandro Böhringer, was useful to the manufacture as long as he kept his energy within proper limits; but, inebriated by the first successes, led more by ambition than by gain, he plunged into speculations, gambling, and frauds. The administrative manager, Pestalozza (who put and end to his life by poison), acquiesced, owing to his weak character, without personal profit. The directors in vain tried several times to call them more stringently to duty; but no one could for a moment have a doubt of their honesty and zeal, and no one outside of the Board ever had a doubt of it.

The report read by Professor Maglione, as curator of the creditors, regards the several periods of the Society from August 1884 to the present time. We will sum up the principal points.

On August 5th, 1884, the board of directors of the Fabbrica Lombarda di Prodotti Chimici asked the Tribunal of Commerce for a *moratorium* (delay to meet the engagements), which was granted.

The balance-sheet of June 30th, 1884, presented a deficit of 1,866,283 f. 29 c. which had to be deducted from the capital; but that balance-sheet was only numerical. On asking for the *moratorium* the Board presented a statement of what it considered the real situation, which, after the loss of the whole capital of 6,000,000 f. presentd the following results:—

	Fr.	C.
Assets...	11,872,576	85
Liabilities	10,919,735	76
Surplus... ..	952,841	09

The details of this situation are as follows:—

ASSETS.

	Fr.	C.
Value of the manufacture ...	2,610,910	21
Debtors...	3,003,695	75
Cash	15,912	76
Land in Columbia	401,441	10
Stocks and shares	9,506	55
Bills...	45,607	64
Due from shareholders ...	169,000	00
Merchandize	5,616,442	84
Total...	11,872,576	85

LIABILITIES.

	Fr.	C.
Bills unpaid	2,427,234	32
Creditors	8,482,766	44
Workmen's fund, &c.	9,735	00
Total... ...	10,919,735	76

The curator had proceeded to a general and rigorous valuation of the assets and liabilities, and it appeared that the situation was much worse; besides the loss of the capital of 6,600,000 f, the deficit appeared to be 5,468,554 f. 43c. The general results are as follows:—

	Fr.	C.
Assets...	12,617,489	29
Liabilities	18,086,043	72
Deficit	5,468,554	43

The details of this situation are as follows:—

ASSETS.

	Fr.	C.
Buildings	404,500	00
Machines, plant, &c.	940,000	00
Lands	610,000	00

Total...	18,086,043	72

It is therefore evident that not only the whole capital is lost, but that the creditors will also be liable to a large loss.

The report presents afterwards the results of the temporary management of the manufactory, which began during the month of August. The production of quinine was reduced from 100 to 30 kilos, daily. The financial results were not unfavourable.

The report says that the management was apparently regular, though an attentive eye would have discovered the hidden irregularity. The alterations in the stores were rather gross. According to the inventory of June 30th, 1883, the stocks of cinchona bark were:—

	Kilos.
Bales in stores, 3,612; containing of sulphate of quinine	6,009·40
Bales afloat, 3,292; containing of sulphate of quinine	6,572·22

On the contrary, the bales in store were only 2,662, with 2,463·66 kilos. of quinine; those afloat were 1,967, with about 2,000 kilos. of quinine. Instead of 12,671·62 kilos. of sulphate of quinine, there were only 4,463·66 kilos.—a difference of 8,207·95 kilos. of sulphate of quinine. Their price being taken at 340f. each kilo., the loss in the situation was 2,800,060f.

In summing up and by clearing those assets and liabilities which compensate each other, the result is the following:—

	Fr.	C.
Assets	4,565,051	29
Liabilities	10,033,605	72

The assets being only 45 per cent of the liabilities. It is, however, probable that the assets may undergo again a slight reduction owing to expenses in bankruptcy, &c.

The report concludes by saying that several creditors have asked for legal proceedings against the board of directors.

The report was received with great attention and general assent. No debate worth recording followed.

Professor Maglione was appointed definitive curator, and the following were returned as delegates of the creditors:—Perelli-Paradisi Antonio, by 42 votes; Alberto Rollier, as representant of W. H. Cole, by 42 votes; Von Willer, by 39 votes; E. Viglezzi, as representant of the Banca di Milano, by 38 votes; E. Rava, as representant of the Banca Generale, by 36 votes.

The *Oil, Paint, and Drug Reporter* has published the following partial (and, probably, not quite accurate) list of large creditors of the company:—

	Lire
Banca Generale (500,000 secured) ...	979,000
Banca di Torino (1,000,000 secured) ...	2,190,000

Banca Italiana Lyano	212,000
Perrier Frères	282,000
Société Marseillaise	250,000

Mr. Boehringer seems to have been a man of liberal views and boundless ambition, backed by a great deal of ability in a direction which enabled him to impress his views upon others, and not only gave him the control of large means but for a time made him the leading spirit in the quinine industry of the world. It is quite evident to the lay observer that Mr. Boehringer was lacking in the qualities necessary to bring his ambitious conceptions to fruition. It is stated by those who have been conversant with his plans that they had been most ably laid but had been thwarted by circumstances beyond his control. This is quite possible, but it will doubtless prove poor consolation to the stockholders in the Company which seems to have been bankrupted under his management, or to the proprietors of other factories who have, in competing with the Milan and its wild commercial policy, been compelled to carry on an almost profitless business. It is stated by those who have seen contracts made by Mr. Boehringer on behalf of the Milan factory that they indicated a business policy which could have no other ending than bankruptcy. His extensive business operations, which gave him a large measure of the personal prestige that he possessed for a time, appear to have been the outgrowth of a determination to sell quinine regardless of price. With reference to the purchase of bark his ideas were evidently sounder, although he was not able to carry them out and he wasted much money in an effort to control the bark market in the interest of quinine manufacturers. His opposition, however, cost the bark speculators, led by Meier & Co., a great deal, and his factory subsequently contributed to their failure as it is understood that the primary cause of Meier's failure is owing to the nonpayment of acceptances given C. G. Meier & Co., by the Milan factory for several thousand bales of bark during the early part of this year. The paper was discounted by Meier & Co., and having gone to protest, it engulfed that house. Another well-known London firm connected more closely with the drug trade is largely interested in the latter failure, but having ample capital at its command will not feel the losses. This is the second time that Meier

& Co., were unable to meet their obligations, similar speculations in 1872 having brought them down. The suspension is only temporary, as they expect to resume at an early date. The same may be said in regard to the Milan factory, so far as the time of suspension is concerned. It is understood to have secured an extension of six months from the Italian National Bank, and will probably be in operation on a smaller scale than hitherto. One of the misfortunes of the factory has been that it had but a limited consuming trade for its brand, and was obliged to seek the open market for by far the greater part of its out-put. A large amount of Milan quinine has in one way and another gone to the United States, but during the past two years there has been no time when many thousand ounces of its product were not held by bankers at Genoa, Milan and other Italian cities, by or London houses. Much money has been lost by the holders of these hypothecated lots, and the fact that they have been hanging over the market accounts for much of the demoralization that has prevailed during the last two years. The capacity of the Milan factory is said to have been popularly over-estimated because the offerings of its quinine on the open market represented so large a percentage of its total product, comparatively little of which disappeared in regular channels of consumption which it controlled. The factory of Zimmer at Frankfort and Boehringer and Sons at Mannheim are said really to equal in capacity the Milanworks. It might be well to mention here that Alex. Boehringer has no interest in the business controlled by C. F. Boehringer and Sons of Mannheim, or the factory of Boehringer and Meier, of Stuttgart, manufacturers of minor chemicals and bottlers of Milan quinine. The bottling arrangement is a joint compact, and was entered into by the Milan factory for the purpose of overcoming any prejudice that might exist in Germany to a quinine having a foreign label.

Mr. Boehringer's scheme of controlling the bark market involved the formation of the quinine syndicate, and the payment of better prices for bark and an advance in quinine with an effort to induce importers of bark not to make advances, thus preventing a surplus which would be a benefit to neither manufacturers nor shippers. The syndicate was dilatory in advancing prices on quinine, although it is understood that many of its members were in favor of an advance, and there has been no time since when the manufacturers of quinine could make up for the profits which they failed to gather in during the existence of the syndicate. As is well known, the syndicate was short lived—its existence having terminated after an experience of eight months. Charges have been made of underhand work, but it devolves upon some one else to confirm them. At all events, the straightforward houses claim to be the sufferers. One or two pages of history in this connection are missing, and probably the unknown will never be brought to light. After the disruption of the syndicate, Mr. Boehringer went to America, arriving here on the day that Powers and Weightman's factory was destroyed by fire. It is understood that his original intention was, in view of the abbreviating of his interests and his influence in the Milan factory, to connect himself with an American quinine factory, but not the one last mentioned. The fire changed his plans, however, and he went direct to Philadelphia and submitted an offer, on his own responsibility, to transfer the factory and stock on hand at Milan over to Powers and Weightman until their factory was re-built. After communicating with the directors of the Italian works, an agreement to the above effect was entered into, and gladly accepted at Milan, as Mr. Boehringer well knew it would be. Doubtless this temporary leasing of the works to the American firm delayed the failure which promptly followed the termination of the lease. Mr. Boehringer is now understood to have retired altogether from the Milan Company in which his interests is reported to have been small for some time past. He has succeeded Mr. Bardorff as managing director of the Verein Chemischer Fabriken, at Mannheim, manufacturers of magnesia and minor chemicals.—*New York Drug Reporter.*

ONE OF THE WOOD-CARRYING MOTHS: A TEA-LEAF EATER.

The following is from a planting correspondent addressed to the editor:—

Kelani Valley.

DEAR SIR,—By this post I send you a "poochie" which I found feeding greedily on the leaves of a tea bush. The "poochie" in question was devouring both old and young leaves from top to bottom of a shoot on a bush pruned about two months ago. Will your entomological correspondent kindly say what it is?—Yours truly, E.

In the absence of our entomological authority from Colombo at the time, we sent the tea-leaf-devouring poochie from a Kelani Valley correspondent to our botanical referee, who reports as follows:—

"Some years ago I sent you a note on the subject of one of the small wood-carrying moths, the female of which entirely denuded flamboyant tree leaves in Kollapitiya, and I got you to copy what Sir J. E. Tennent said about these peculiar insects in his *Nat. Hist. of Ceylon*, pp. 430-2, and I do not think you can do better than reproduce the same matter with a full list of this family from the *Lepidoptera of Ceylon*, pp. 101 to 107, all of the species, 9, being illustrated in plate 118 of that work; but the information given respecting popular or useful information in this work is so meagre, that a searcher after such must depend much on his own experience or inward consciousness as to his conclusions on the subject. I am quite familiar with the billet of wood-cases of some of the females of these moths, and a friend brought me some from Ambagamuwa a few days ago, which soon took to climbing to the roof of my bathroom, &c. The very curious figures given by Sir J. E. Tennent of four of these ingeniously-made up houses for the females are not referred to by Moore, though he quotes a portion of the letterpress. Tea-leaves were not dreamt of in the philosophy of these insects when they were described and figured, and therefore, out of the nine species found in Ceylon, it is recorded that two of them feed on the leaves of the pumpelmos or shaddock, and a third on *Eugenia caryophyllæum*; and the other figures are so unlike the one that ate the flamboyant leaves, that I think it has not as yet been recorded.

"But pardon me if I express surprise at the apparently extraordinary propensity which now exists for the discovery in Ceylon of enemies to all kinds of new or old products whilst the old facts still hold good that the great Creator of the universe will bring 'blasting and mildew on the land' when it is necessary to do so for the balance of Nature as He has done from the time that the taste of that forbidden tree brought death into the world.

"Your correspondent's poochie is most like the figure of the *Eumeta Layardii* in plate 118, fig. 2*a*, in the larval case, and the principal figure in Sir J. E. Tennent's plate. The insect seems so easily discovered on tea plants, that there should not be much trouble in collecting them and squashing them under foot. I do not think that this large one will prove a great enemy of the tea plant; some of the smaller ones may, if they take to tea instead of their usual food.

(*From Sir J. E. Tennent's Natural History.*)

The Wood-carrying Moth.—There is another family of insects, the singular habits of which will not fail to attract the traveller in the cultivated tracts of Ceylon—these are moths of the genus *Oiketicus*, of which the females are devoid of wings, and some possess no articulated feet. Their larvæ construct for themselves cases, which they suspend to a branch frequently of the pomegranate, surrounding them with the stems of leaves, and thorns or pieces of twigs bound together by threads, till the whole presents the appearance of a bundle of rods about an inch and a half long; and, from the resemblance of this to a Roman fasces, one African species has obtained the name of "Lictor." The German entomologists denominated the group *Saecktrager*, the Sinhalese call them *Dara-katteya* or "billets of firewood," and regard the inmates as human beings, who as a punishment for stealing wood in some former state of existence, have been condemned to undergo a metempsychosis under the form of these insects.

The male, at the close of the pupal rest, escapes from one end of this singular covering, but the female makes it her dwelling for life; moving about with it at pleasure, and entrenching herself within it, when alarmed, by drawing together the purse-like aperture at the open end. Of these remarkable creatures there are five ascertained species in Ceylon: *Psyche Doubledaii*, Westw.; *Metisa Plana*, Walker; *Eumeta Cramerii*, Westw.; *E. Templetonii*, Westw.; and *Cryptothelea consorta*, Temp.

(*From Westwood.*)

The genera Oiketicus and Psyche are remarkable for the habit which their larvæ have of constructing for themselves portable cases of bits of grass and sticks or leaves' in which they reside, and undergo their transformations. The transformations of these insects are especially interesting, and the females are entirely apterous, being in fact the most imperfect of all Lepidopterous insects; and even less favoured than their larvæ, which they considerably resemble. I possess some very singular cases, formed by exotic species of these genera. The male larva of Psyche, previously to assuming the pupa state, fastens its case by the mouth to the surface of leaves and stems of plants; the larva then turns, so that its head is pointed towards the opposite aperture, out of which the pupa half pushes itself before becoming an imago: the females, on the other hand, never leave their cases; and from some observations made by Ochsenheimer and Ingpen (*Steph. Illustr. Haust.* 2. p. 81.), it would appear that these females produce fertile eggs without fecundation.—The relation of these insects with the Ægeriæ seems confirmed by the Sphinx ephemeræformis, an insect which Mr. Stephens has formed into the genus Thyridopteryx, next to Psyche. (*Trans. Entomol. Soc.* vol. i. p. 76.) M. Rambur has described another genus, under the name of Heterogynis, which seems intermediate between Psyche and Penthophera, agreeing with the former in the general appearance of the male, and the apterous inert female; but having a naked larva, which makes a cocoon somewhat like that of Anthrocera. (*Ann. Soc. Ent. France*, 1836, pl. 17., and *Fauna Andalus.* vol. ii. pl. 14.)

(*From the "Lepidoptera of Ceylon," pp.* 101-167.)

FAMILY PSYCHIDÆ.

(1) *Eumeta Cramerii* (plate 118, fig 1, male, 1*a*, larval case), p. 102. *Oiketicus Cramerii*, Westwood; *Cryptothelea consorta*, Walker; *Eumeta Nietneri*, Felder. Larval case covered with slender twigs of irregular length, which are disposed longitudinally side by side in a somewhat spiral form.

(2) *Eumeta Layardii* (plate 118, fig. 2, male 2*a*, larval case), p. 102. *Eumeta Cramerii*, Walker, not Westwood. Larval case covered with stoutish twigs, which are disposed side by side in a regular longitudinal form.

(3) *Bambolina consorta*, (plate 118, fig. 3, male, 3*a*, larval case), p. 103. *Oikiticus* (*Cryptothelea*) *consorta*, Templeton. Larval case of a lengthened conical shape, formed of compact greyish-white silk, occasionally with a few particles of twigs on the surface. "Larva feeds on Pamplemos bush (*Citrus decumana*)."—"Templeton."

(4) *Duppola Templetonii* (plate 188, fig. 6, male, 6*a*, larval case), p. 104. *Oiketicus tertius*, Templeton; *Oiketicus Templetonii*, Westwood; *Eumeta Templetonii*, Walker. Larval case bluntly fusiform, silky, naked. "Larva feeds on *Citrus decumana*."—Templeton.

(5) *Manatha albipese*, Moore (plate 118, fig. 4, male, 4*a*, larval case), p. 105. Larval case conical, small silky, slightly covered with pieces of thin bark or lichen, the specimen under examination having the heads of six (or more) young larvæ protruding from the upper end, one (the largest) from an extended sack in the middle, the others from separate sack-like openings below, and around the upper one; from the larva end of this same example protrudes the empty pupa case from which the perfect insect (? female) had escaped.

(6) *Metisa plana*, Walker (plate 118, fig. 9, male), p. 105. [A tiny moth only.—W. F.]

(7) *Chalia Doubledayii*, Moore (plate 118, fig. 5, male 5*a*, larval case), p. 116. *Oiketicus Doubledayii*, Westwood; *Psyche Doubledayii*, Walker. Larval case slender, silky, with a few very thin twigs arranged longitudinally on the surface.

(8) *Aprata Thwaitesii*, Moore (plate 118, fig. 7, male, 7*a*, larval case), p. 107. The larva constructs a small flattened hiliciform [shell-like.—W. F.] case. "Feeds on *Eugenia* (*Syzygium*) *caryophyllæum*" (*Thwaites*).

(9) *Aprata Mackwoodii*, Moore (plate 118, fig. 8, male), p. 107. [This is the type of the genus. A tiny moth only.—W. F.] In the original descriptions of some of these by Mr. Moore in the Annals and Magazine of Natural History, the Hon. Mr. Mackwood, one of the most industrious collectors of Ceylon Lepidoptera, is acknowledged as the authority for the specimens described, but in the Ceylon Lepidoptera, which are reproduced from drawings made by Mr. Alwis, the draughtsman of the Royal Botanic Gardens, Peradeniya, under the inspection of the late Dr. Thwaites, no reference is made to the authority for the original specimens from which the genera and species were described.

"In the foregoing I have copied the names and synonyms and the authorities for them, leaving out the references to the works in which they were separately described."

TEA CULTIVATION AND ITS ENEMIES.

From the fear excited in some quarters at the least reference to an actual or possible enemy of any one of our new products, it would almost seem as if merchants and other capitalists interested in Ceylon had forgotten the absolute condition under which agriculture all over the world, in its broad aspects, must be carried on. "In the sweat of thy face" is the condition of cultivating the soil given in the old Book, and it is true still, whatever exceptions there may be in occasional rich returns out of all proportion to the labour bestowed and the capital risked. At the same time if there be that hard condition of labour in the old Book, no less clear is the promise there of seed time and harvest never failing. No doubt the experience of the coffee fungus has been a most terrible, even ruinous, one and men do pay attention to the proverb of "once bitten, twice shy." But why, because coffee is affected in Ceylon, it should be supposed that cacao, tea and other products are bound to fall after the same fashion under the first enemy which may be reported as troubling them, it is impossible to see. In fact the argument ought to be the other way. Surely, it is not in the order of providence or natural laws that a country afflicted with a dire pest peculiar to one product, should be visited with other similar pests on whatever new products may be started? It was rightly argued in connection with *Hemileia vastatrix* that never in history had a great agricultural industry been killed out by a fungus or other enemy, and this may be proved true yet even in the case of Ceylon; but still more unheard-of is it that a variety of agricultural industries should be supposed to be liable in one and the same country, to insidious and absolutely fatal blights. And yet we are aware that at the least reference to the discovery in Ceylon of an enemy of cinchona, cacao or tea, the London capitalist is apt to button up his coat, shake his head and declare he will have nothing more to do with this Colony and its new or old enterprises! We found a London merchant (with Ceylon experience too) only a few months ago beat on stopping all work in cacao planting, because of a single mail's budget with the reports of an enemy and the work it had done. At the same time our friend was jubilant over his tea crops and sales. But when another mail reaches "the City" with the news of "Helopeltis" and "Red Spider," very possibly the cry will be:—"No more expenditure on tea extension,—'ca' canny'; let us see about this new enemy (another fatal fungus in disguise perhaps)"! Now we should like such fearful, unbelieving and illogical individuals to invest in a copy of "Nietner's

Enemies of the Coffee-tree" published at this office, and read over the hundred-and-one enemies of coffee which prevailed in Ceylon twenty and thirty years before the *Hemileia* fungus was ever heard of. So with the "pouchies" on tea and cacao, as in fact with the big caterpillars (seasonal "gooseberries") which used to be served up to us, editors, when cinchona cultivation first became general. It is a wise and proper thing to take notice of all enemies, even the most minute, to study their habits and the best way of checking their work. The Press in Ceylon, agricultural in its work above everything, must take cognizance of all such pests; but we beg of our readers in Colombo and outside of the island not to run away with the idea, that each new discovery or report of an enemy sounds the knell of the particular product concerned.

It was inevitable that here in Ceylon as in India previously, the increase of tea cultivation should be followed by the appearance of the insects which specially feed upon the plant. About the most troublesome are *Helopeltis Antonii* and the mite known popularly as "red spider." They are present in Ceylon, but not to any large extent and we do not think that tea planters at all have need to be alarmed. In India there has never been anything like a wide-spread and general attack on estates, the creatures being local, and capricious as to season and other circumstances. When they do haunt an estate, or a group of estates, they (especially *Helopeltis*) undoubtedly can do mischief: but as we have said their ravages are never widespread or general, nor are they long-continued. The creatures come and go but never prove fatal to the plants, and at the worst only decrease their yield for a season. We now know a great deal more than did the Indian tea planters some years ago about modes of reproduction of the pests, so that it will be the fault of planters here themselves if they are not largely successful in diminishing the evil. There is no possible comparison between the *permanent* mischief done by the insects on tea and the fungus blight which has dealt so cruelly with our coffee.

As a matter of fact we are aware that both *Helopeltis* and Red Spider, although not publicly reported at the time, have been identified on Ceylon Gardens so far back as a year ago. We learn from Mr. Wall that he found the *Helopeltis* about that time in a low-country district, but it has given little trouble so far, while Red Spider according to the same authority is more troublesome to coffee in some districts than to tea. All the same we trust the fact that these and other new and old enemies are reported on our products from time to time, may not raise the absurd notion that in each case a repetition of our experience with coffee is to be expected! Coffee was extended under conditions which can never again prevail and yet it took forty years before the dire fungus undermined confidence in this—the then one great—planting staple. Remembering how tea, even if it becomes "King," is certain to be varied and supported in our planting districts by other products, we do not see why, even in forty years to come, we should fear any special decadence of our industry in tea cultivation.

PLANTING IN PERAK AND THE STRAITS SETTLEMENTS.

(*By an ex Ceylon Planter.*)

PREJUDICES AGAINST THE STRAITS SETTLEMENTS—PENANG—POPULATION—CONVEYANCES—JINRICKSHAS—THE FIRE BRIGADE—PERAK—COFFEE, TEA, &C.—LABOR—PROSPECTS OF EMPLOYMENT.

Perak, 14th October 1884.

Most people in Ceylon entertain a strong prejudice against the Straits Settlements proper, and, more especially so, against the Protected Native States. The only reasons I can assign for this are, that both the Settlements and the States are to a great extent *terreaes incognitae* to the majority of folk; and that those who are thus prejudiced have formed their opinions from the reports of a few malcontents who thither came, saw, and left very shortly afterwards.

It is not my intention to enter into an elaborate defence of "these parts," but merely to give you a few facts concerning them, so that your readers can judge for themselves; and, with this end in view, I will begin from the very beginning. The journey hither (out-of-the-way place as it is supposed to be) is to say the least of it not an unpleasant trip. The passage to Penang in a P. & O. steamer I need not describe; but Penang itself deserves mention. The approach to to it from the sea is very picturesque with the luxurious palm groves of Province Wellesley on one side of the Straits, and the town with its background of jungle on the other. But it is when in the town itself that one actually realizes the change from Ceylon. True, one sees a great many Tamils (Klings they are called here), but one rather misses the Sinhalese; however, this deficiency is amply atoned for by the large numbers of Chinese, Malays, Sikhs and others who throng the streets. Of the town I will only speak by comparison thus: it is not so pretty as Colombo, nor should I say, its wholesale business is so great. *Per contra*, its streets are more crowded than those of the Colombo Fort, and I think it could give the latter place a degree or two in the matter of heat.

Amongst the things which strike the new arrival are its means of locomotion, and, if one is fortunate enough to see it, as was your correspondent, its fire-brigade. I will treat of the former first. The "gharries" are mostly very poor concerns, and they are drawn by ponies that look out of all proportion to the conveyances to which they are harnessed, Once behind them, however, one is very agreeably surprised at the rate at which these little creatures travel, with loads to drag, apparently heavy enough for a team.

Then there is a vehicle which deserves special mention. I allude to the "jinrickshaw," and for the information of those who have not seen it I will briefly describe it. It is a two-wheeled, hooded, light little trap, something like a small Norfolk-cart with larger wheels, and it is drawn by a Chinaman. It is so balanced that when in motion, the shafts point slightly upwards, and the weight of the passenger or passengers inside, being a very little behind the axle, has a tendency to increase their upward direction; but they (the shafts) are kept in position by the trusty Chinese "horse," who thus instead of bearing a burthen, is by leaning on the shafts partially lifted himself; and he travels with the whole concern at a very respectable pony-trotting rate. It is a turnout which I should say would score a decided success in Hyde Park during the season.

The ringing of bells, and the firing of cannon, as fire alarms, which happened twice during my first night in Penang, naturally brings me to the "Volunteer Fire Brigade" as I saw it the following day. I am not sure, whether these gallant heroes had assisted in extinguishing the actual conflagrations during the night, but I think not. However, there can be no doubt, that their zeal was heightened by these occurrences; for, fully accoutred in the heavy dress of the English fireman, with helmet and hatchet complete, they turned out the following afternoon with a small fire-engine, and had "drill." After a great deal of bustle, shouting of orders, and no little delay, several lengths or coils of hose were unrolled, laid along the ground, screwed together at the joints, and the nozzles affixed—forming, when completed, two fairly long hoses. The men then took their stations, two at each nozzle, and the rest anywhere, all perspiring freely and looking uncomfort-

ably warm. The word was then given to "turn on the water," which was done, and the little steam-engine began to work furiously. The expectant crowd around looked on with breathless interest as one of the hoses slowly began to fill out. Then the other hose followed suit, a little slower. At last, both were full, and one expected every second to see two bright jets of water flashing in the rays of the setting sun; but no such thing followed; the only appreciable result being two small flat and stale streams of water, dropping straight down from the mouth of each muzzle on to the boots of the men who held them. The orders was then given to roll up one hose, which was done with a great deal of screwing and unscrewing, rolling and unrolling, free perspiring and hand-dirtying on the part of the "firemen," together with a frequent tramping in and out of several two-inch puddles, quite regardless of shoe-leather. Well, the water was turned on to the single hose, and the result was a small jet of water, thrown some 10 to 15 feet beyond the length of the hose. After the man with the wet boots had amused himself by wetting a few natives, who invariably came within range, the hose was rolled up and packed on the engine, to drag which back to the police station several natives were captured from the crowd. Then the gallant "firemen" dispersed, and for some little time afterwards might be seen at hotel bars, and such places, refreshing themselves after their arduous exertions. Truly, the whole thing was edifying, and though, at present, I should not think the "V. F. B." would be of great assistance in putting out a decently large fire, still, their drill is amusing. Let it not be thought I am making fun of them, or running them down. Quite the contrary. The movement is a very laudable one, and should be encouraged. With more attention to the matter of drill, and an overhauling of the little fire-engine I have no doubt they will soon render very valuable assistance when their services are required.

The journey from Penang to Perak is performed by small steamers which leave the latter place at 9 p.m., and arrive at Matang (Larut) in Perak, at about 6 a.m. the following morning, and from thence the traveller can proceed to his destination in a two-wheeled gharry, drawn by one of the ponies before mentioned. The cost of the passage in the steamer is only one dollar, and the accommodation, for Europeans, consists of a long-armchair under an awning on deck, in which to pass the night, with a cup of hot coffee in the morning, shortly before reaching the landing-stage. For natives the accommodation is the "softest plank" they can find for themselves, and they lie thickly around one: which fact, and the rainwater trickling through a rather leaky awning, are the only disagreeables I have to chronicle. For ladies, I believe special cabin accommodation can be secured in the largest boat on the line.

From Larut, a drive of eight miles, mostly through low-lying, marshy country, brings one to Thaipeng, which is fairly large town, and the residence of the Assistant Resident. The Resident of Perak has his head-quarters at Kwala-Kangsa, about 22 miles from Thaipeng—a much smaller place than Thaipeng is at present; but one which will, in course of time, outgrow the latter and become a very large town; for it is connected by river with the principal tin-mines, and it will undoubtedly be the centre of the coffee and tea industries of the future.

Coffee grows well and luxuriantly in Perak, bears heavily, and is, apparently, free from leaf-disease. Tea flourishes, and the rainfall and soil on the hills are all that could be desired for successful and remunerative cultivation. Suitable land for other products, such as cocoa, tobacco, rubber, vanilla, pepper &c. is available. The jungles contain valuable timber, and the climate is a healthy one. Labour is dear at present, about double the Ceylon rate; but it will be very much cheaper shortly, as a law was recently passed which permits free immigration of Tamil labour from the southern coast of India.

I would not have it understood that I am advising Ceylon men to come and settle here. I merely speak of the country as I have seen it. It has undoubtedly great advantages, and great capabilities; but for anyone to start planting here, as everywhere else, capital is indispensable. It would be of no use for men to come over "on spec," as employment is not easily obtained; but a man with, say, £1,500—might certainly, in my opinion, go farther and fare worse.

There is very little more which I can tell you about the place, at present, except that it is "growing." Under the Administration of the present Resident, a *progressive* policy is being followed, and amongst other important, and useful public works which are being undertaken, many roads are now in the course of construction, which will open up the country to a large extent. You will hear from me again later on.

KAREP.

ENSILAGE IN INDIA AND THE TROPICS.

We have seen so many doubtful statements regarding the process of preserving fodder by pressure in air-tight pits, that we have long refrained from quoting any of the accounts which have reached us in the papers with which we exchange. But we feel bound to make an exception in favour of a communication to the *Madras Mail* from Mr. H. L. Johnston of Beypore. The cost, in this case, seems trifling, and there is the statement that coarse grasses mixed with better kinds had been greatly improved by the process. Those planters upcountry, therefore, who live near patauas could cut and mix the natural grasses with guinea-grass, *Reana luxurians*, &c. Interest in this matter has diminished since estates have almost universally given up keeping cattle for manure. But, besides milch cows, there are still bullocks for cart traffic on a good many estates. The account we quote may also be useful to estate owners and native cultivators in the low-country as well as the high:—

AN EXPERIMENT IN ENSILAGE.

Mr. H. L. Johnston writes from Beypore:—

"Saurkrout! Saurkrout!! What is good for man is surely good for beast; I'll try it anyhow." So spoke a German farmer one very wet summer, some eighty years ago. Substituting grass for cabbage, leaving out the peppercorns, and using a hole in the ground for the family crock or barrel, a very good fodder was obtained. Such has been given as the origin of ensilage. The preservation of fodder in silos by this system is extremely simple, and should demand the attention of all who keep cattle, more especially planters, and those who maintain large herds for breeding or manurial purposes, and who have doubtless, in common with myself, experienced the difficulty and expense of keeping cattle in anything like fair condition during the hot months, more particularly in those districts where annual forest fires occur. The following details of an experiment made last year may be interesting to those who wish to give the plan a trial.

I excavated a pit 10 feet by 6 feet by 6 feet, in fairly hard soil, rough plastered the inside with chunam, and roofed it with cadjans;

Costing	... R12	8	6
Cutting, filling, and weighting	... „ 5	8	6
Total	... „ 18	1	0

All grass was purposely cut, and carried in pouring rain. The pit or silo was first filled in July and weighted; sinkage two-thirds. In August it was filled up at intervals and finally closed; nearly four tons of stones, earth, &c. piled on the coveriue boards, and the silo left till April this year. The sinkage was then found to be 20 inches. About three

inches of grass under the boards was rotten; all the rest in good order, but not so moist as I expected. It weighed 30 lb. to the cubic foot. I had then three tons of fodder, costing R6 per ton. Cattle took to it at once. It would not have cost me more than R3·8 to R4 per ton had I repeated the experiment this season. The following particulars, will, perhaps, be found useful :—

Kind of Grass.—About 40 per cent of Huryali; the rest tussock, and other coarse grasses. The land on which the grass was grown is quite bare in the hot weather. I believe anything green will make ensilage.

How put in? and how much at once?—Bundles untied thrown in and well trodden down. As much as you can.

Covering boards.—2 inches thick; length equals the breadth of the pit.

Weight.—Put on some weight whenever you stop work.

Kind of weights.—Concrete blocks 9" × 9× 18" are used in England.

In a recent number of the *Field* notice is taken of a patent in which a simple mechanical principle is made use of. The machine is called the Ensilager. Price £25 for a silo 50 feet long; stones areas good as anyting.

Mats.—General Wilkinson's suggestion to use date mats between the grass and boards is a good one.

How long between each filling? Immaterial, if weights are on.

Foreign substances mixed in.—Nothing necessary; salt might be used to insure the cattle getting it.

Chopping of material.—A freer use use of the chaff engine than is considered necessary in England may be advisable. Maize, Guinea grass, Sorghum and Reana, &c. especially.

Color—Pale yellow green, turning brown after exposure.

Is the pit air tight?—There is nothing to make the pit air tight except compression by the weights.

How much removed at once?—Enough for the day, a slice one foot wide or so, should be cut right down at the lower end. It can then be sliced off like cutting a hay-rick; weights should be kept on the remainder till wanted. The *Field* says no change takes place under a week.

How drained?—I sloped the floor four inches to one corner and made a small well. This should have been stopped up till the cutting began, then opened to allow the ooze to run off. Monsieur Gaffart, in his "*Manuel de l' Ensilage*," says "If water gets into the silo, whether from without, or as the result of pressure put on maize, that is very full of moisture at the time of ensilage, take care not to let it be wasted. The beasts drink this kind of vegetable soup with great avidity, and thus all loss may be avoided on this head."

Cost and Construction.—This of course depends on the local cost of labour, the nature of the soil, roof, &c. A lining of brick work, run over with cement, would be an improvement. In my opinion the sides should be perpendicular, otherwise the covering boards would be disarranged during the sinking. It would be as well to consider, when making a silo, what the daily requirements of the herd are, so that one or more complete slices would suffice for the day

Rations.—Fifty pounds a day is set down, and this appears to be ample. In feeding cattle I have noticed that they eat every bit of it. There is absolutely no wastage; the coarse or rank grass seems to be rendered palatable by the process.

While on the subject of cattle food may I draw the attention of the Secretary of the Society for the Prevention of Cruelty to Animals to the Government order relating to feeding charges on impounded cattle. One anna per day is all that is allowed for a horse, bullock or cow, &c.; it is pure starvation as things exist in these parts.

PLANTING IN SOUTH WYNAAD.

EXPERIMENTAL CULTIVATION OF THE NEW PRODUCTS—TEA AND FIBRE—REVISION OF THE SETTLEMENT—JUSTICE TO THE PLANTERS AND NAYARS.

VYTHERY, Oct. 18th—Whenever the coffee and cinchona markets are depressed one hears a good deal about the capabilities of the Wynaad for growing other products—tea, cardamoms, rhea, tobacco and the rest; the fact being that almost any of the industrial plants that require a tropical climate will grow here luxuriantly. But a rise of a shilling or two in the price of coffee sees us off on another tack, and everybody talks of the difficulty of procuring labour when it is most wanted for tea, and of endless troubles the cardamom grower has with the jungle tribes. The present depression has, however, been so long continued that there are some signs of planters here being seriously on the look out for something new to open land with, and your recent article on tobacco cultivation has been read with a good deal of interest. The writer does not state for how many years in succession the land planted in the way he recommends can be cropped; and as tobacco is extremely exhausting to the soil under ordinary conditions, and land is becoming scarce in Wynaad this point is of importance. As for tea, its success in Ceylon ought to stimulate us into planting it, especially as Wynaad is said to be peculiarly fitted to grow it; indeed it is already doing very well in the few places where it has been tried; and a planter from the Kangra Valley, who visited us last year, was surprized at the growth of some trees he saw. There appears, however, to be a general feeling of doubt as to whether the Ceylon planters are not overdoing the thing, as they did with cinchona; and we are waiting for further news as to the average yield of tea planted on abandoned coffee land, as the estimate of 700 lb. per acre made by the *Observer* beats almost anything we have heard of, even on new soil, and in the exceptional case of the Mariawatte estate which you quoted lately, it appears that the land is at a low elevation, and has great facilities for heavy manuring. Messrs. Parry & Co. have some land of this kind planted with tea near Vythery, but though the tea is very good, and is generally drunk in the district, I believe the outturn is not sufficient to show much profit. Moreover, while it is possible to make a coffee estate, however small, pay for its working, it is of no use to go in for tea, unless one is prepared to open largely, so as to keep the expensive machinery pretty constantly at work; and financial reasons keep Wynaad men from "plunging" just at present. Some trial plantings of fibre have been made this monsoon, principally of the wild rhea, or kurry kuddy, as the natives call it. The fibre produced from it has been valued at about £40 per ton. It grows here naturally; but planting it from roots has proved too expensive, and cuttings do not seem to do well, so it will be necessary to collect the seed, and form nurseries of it for next year if it is to be largely grown. I hear that the "Glenrock" people are putting up machinery to treat the bowstring fibre, which grows in great quantities on some land they have acquired. It is to be hoped that this, the first attempt made in these parts to collect our natural fibres on a large scale, will be a success. If, however, the experience of some planters here is a criterion, the "Glenrock" people will find that the expense and trouble of collecting the plants from a large area, and bringing them to a central mill, are very great.—*Madras Mail.*

THE TEA-MITE AND THE TEA-BUG OF ASSAM.

A very opportune work has lately made its appearance, in which the author, Mr. Wood-Mason, of the Italian Museum, tells us all that he has, after careful research, been able to gather respecting the formidable pests mentioned above. The work is rendered all the more valuable by several admirably finished colored plates, showing the pests enormously enlarged, and giving, thus, a very tangible idea of the destructive capabilities of these enemies of the tea plant. It is difficult to say which of the two is the more deadly. The tea-bug or mosquito blight attacks the young shoots, which then curl and dry up, while the red spider more particularly confines its ravages to the full-grown succulent leaves. A curious circumstance in connection with both these forms of blight is, that neither of the two has yet been met with on any other plant,—at least, so says Mr. Wood-Mason; but some planters dispute this, and we should be inclined to think, also, that the tea bush is not the only plant patronized by these gentry.* The difficult matter in applying any remedy for red spider is, that the eggs are laid in *hollows* close to the ribs of the leaves, and are not scattered over the whole surface, so as to be at once perceptible and get-at-able. Although heavy rain is one of the best antidotes, still the eggs are so firmly attached to the leaves, that it requires a good deal of continuous downpour to wash the eggs away, and even then the spider itself takes shelter underneath the leaves, and is thus on the spot ready to commence anew. When at Darjeeling some years ago, we visited a garden there heavily afflicted with red spider; and going out after a heavy downpour of rain, we picked several

* It is only recently that *helopeltis* has been identified on cacao plants in Ceylon, but it seems very extraordinary that Mr. Wood-Mason should never have heard of the long-continued and serious attacks by this insect on the cinchonas in Java.—ED.

leaves and placed them under the microscope, when it was seen that though many eggs had been washed off, a good many still remained; the spider itself was in such cases seen on the underneath portion of the leaf, almost as free from wet as if it had been under an umbrella, as it were, which Nature had kindly provided.

There appears absolutely to be no remedy for spider blight. In fact, if there were, it must necessarily be most difficult of application over anything like a large area.—Syringing with muddy water has been recommended, and for the time it has seemed to be efficacious, but as the eggs revive under the influence of the sun, the relief is only partial; besides which, it is difficult to apply such a remedy over a large area. Some have propounded the theory that the red spider only attacks weakly plants, and therefore that nutritious or well-manured soil is all that is needed. No doubt, to a certain extent, this is correct, in so far that a strong and healthy plant will better be able to recover from a partial attack than one growing on impoverished soil; but it is hardly likely that the spider should prefer old and exhausted, to young and vigorous plant. We believe that, on one estate, "burning" was tried on a bad patch, and with success; but as a matter of fact, any *real* remedy remains to be found; and so far as this goes, Mr. Wood-Mason's book has not advanced matters much. However, it serves the good purpose of recalling attention to a very important subject, and he tells us clearly and plainly all that is at present known on the subject.

Planters might do good service by variously experimenting on small patches of bushes affected by spider blight and recording their experience carefully. Spider blight, has come almost to be looked upon as so inevitable a misfortune, that planters have, perhaps, become somewhat too prone to *accept* the "inevitable" as such.—*Indian Tea Gazette.*

[As to a remedy, we have marked a passage from the London *Times* regarding a mixture of oil, kerosene, quicklime and water, found effectual in the case of the phylloxera on vines.—ED.]

THE TEA MITE AND TEA BUG.

The *Indian Agriculturist* contain some further extracts from the recent work by Mr. Wood-Mason, and the question of *Helopeltis Antonii* being indigenous to Ceylon appears to be set at rest—indeed it seems strange it should ever have been raised, in view of the statement that the name was given to *a Ceylon insect* described and figured a quarter of a century ago (that is in the time of Dr. Thwaites!) by the French entomologist Signoret.* It is true that Mr. F. Moore considered the tea bug of India a distinct species which he named *H. theivora*, and under this name Mr. Mocns, in his earlier reports, mentioned the insect which attacked the Java cinchonas Ultimately, however, he and his colleagues used *H. Antonii* as the proper name, convinced, we presume, of the identity of the insect which attacked cinchona and tea in Java and tea in India with the Ceylon insect described by Signoret But, surely, in the annals of science there is nothing more curious than that the Ceylon insect described by a French entomologist (if from Ceylon it reached him,) should never have been observed by so careful a naturalist as Dr. Thwaites, and that his successor, Dr. Trimen, in recording his researches into the life history of this very insect, should have expressed doubts as to its being indigenous. This insect, like the coffee fungus, must have possessed in a wonderful degree the power o concealing itself from observation, until the time for its effective début in force had arrived It will be interesting now to trace the source whence Signoret obtained his specimens. Scarcely from Mr. Nietner, for, surely, *he* would have described the creature himself. And yet it must be remarked that Nietner devoted special attention only to the insects which could be classed as "enemies of the coffee tree," and we know that he sent entomological specimens to Germany, whence they may have reached France. Here is the distinct statement in Mr. Wood-Mason's work :—

THE TEA-BUG OF ASSAM.

The tea-bug is so closely allied to a Ceylonese insect which was described and figured a quarter of a century ago by the French entomologist, Signoret, under the name of *Helopeltis antonii* as to have been considered by no less an authority than Professor Westwood to be only a variety of it. Mr. F. Moore, formerly Assistant Curator of the East India Company's Museum, however, has expressed the opinion that it is a distinct species, and has bestowed upon it the appropriate name of *H. theivora*. Five other species of the same genus—namely, *H. nigra*, and *H. braconiformis* from Waigion and New Guinea respectively, *H. pellucida* and *H. collaris* from the Philippines, and *H. podagrica** from some unknown locality—have been described at different times by various entomologists, and considering how excessively meagre our knowledge of Asiatic capsidæ is, it is probable that several more remain to be discovered in the vast and imperfectly explored region lying between the extreme limits of its ascertained distribution.

The tea-bug is therefore a member of a genus of capsidæ which is characteristic of the Indo-Malayan fauna, and extends in its distribution from North-Eastern and Southern India (including Ceylon) through the Philippines to Waigion and New Guinea; and in the absence of evidence of its occurrence in any other region, we must consider it to be the North-Eastern Indian representative of the genus, and that it has not been introduced, but that it is truly indigenous to the country in which we find it—a view which is confirmed by many parallel cases in the geographical distribution of animals.

The merit of being the first to discover the *Helopeltis theivora*, and to bring it to the notice of entomologists and of planters, belongs to Mr. S. E. Peal, a planter of the Sibsagar district, in Upper Assam, who has published an excellent paper upon its ravages, in which he demonstrated that the so-called "spotblight" was the work of this insect, Mr. Peal thus describes the ravages caused by this pest:—

"The general view of the tea is that shoots are all brown, withered, and in fact dead, and the tea presents a generally brown look, instead of the bright healthy green that is usual.

"On examining a tree so affected, if the blight has only recently affected it, the appearance is very different from that of a tree which has suffered some time. In the former case the general growth and the look is normal, but the youngest shoots and tips are more or less spotted with brown, the size of the spots varying with the age of the insect. If the bug is very young, the punctures are close and minute and the discolorations coalescent, but if it is full-grown, the spots are larger, say an eighth of an inch in diameter. Again, if the punctures are recent, the colour is pale brown and darkest at the edges; but if one or two or more days old, the spots are dark brown verging on black, the entire leaf curling up and withering completely if they are close.

"In the case of a tree that has suffered some time, and severely, the symptoms are often less visible at first glance; the dead leaves have mostly fallen off and the minute shoots at the leaf-axils alone show the damage, and all are dry and dead, there is less dead leaf showing, and in its place we find dead 'tips' everywhere.

"A more careful study will often show a still more unpleasant fact, *i. e.*, that ere it ceased entirely to shoot out, the tree had made many efforts to grow, all of which had been rendered abortive; and a branch that has not yielded one single leaf or tip will present all the appearance of having been very severely and persistently plucked.

"On the tips of the young vigorous shoot being punctured, it has died as certainly as if nipped off, and the eyes below in the leaf-axils shoot out vigorously, and ere the bug can do serious damage one or two shoots have

* The only question is whether there may not have been an error as to the source whence the specimens were derived: not very probable.

* The tea-bug has gouty swellings up the thighs, and may possibly be this insect.

attained some size and carry several leaves but as the insects increase in size, these tips again are attacked, and other shoots start from other eyes, though attaining a less vigorous growth, and in a short time we have a 'broom' where not one leaf or tip has been taken by us, but has been killed off or sucked dry by the bug alone: drawings of such I send herewith to illustrate. When this is the case, growth will have come to a complete standstill, as every shoot requires from (say) forty to fifty days to mature from an eye to be fit to pluck. We may say the trees shut up for about two entire months at least, and is specially unfortunate that this takes place usually about mid-season, and when we should be doing our very best. I do not state that the entire garden is thus affected at once, or we should soon see tea itself at a standstill, but the particular patches and trees most blighted are so as before stated. It is difficult to tell what part will be attacked this year or next: all places seem pretty equally liable to blight, and, unless very bad indeed, it is seldom seen, as yet, over an entire garden at once; but that this will be the normal state eventually I do not doubt. The recovery of the tree is slow, unless pruned, and this is about as bad as the disease, as far as our outturn of crop is concerned."

And now Mr. Wood-Mason describes his important discovery of the mode in which the creature deposits its eggs, a knowledge of which ought to give planters of the present day a great advantage :—

It was reserved for me to dicover the manner and position in which the tea-bug lays its eggs; and a brief but sufficient account of my observations is given in the following communication addressed by me on June 8th, 1881, to the Chief Commissioner of Assam, by whose orders it was published in the *Assam Gazette* for general information :—

"Tea-Bug.—Have discovered, by observation of specimens of this formidable pest kept in confinement, that the female deposits her eggs singly in the substance of the tenderest shoots of the plant, in the internodes or portions of the stem between the pekoe and the two or three leaves succeeding from above downwards, and in the buds developed in the axils of plucked leaves and in the parts thereabout; that the presence and position of each egg is from the first indicated on the exterior by two unequally long, glistening, white, bristle-like prolongations of its shell, and later by discoloration of the point pierced. Have discovered by dissection that she is provided with a serrated ovipositor, of the shape and sharpness of a sabre, wherewith to pierce holes in the soft tissues of the plant for the reception of her eggs. These observations have been verified in the field upon numerous blighted bushes; but, though eggs have readily been found by the unaided eye on blighted portions of bushes, not a single one has yet been seen on any perfectly uninjured shoot. The vigorous and unremitting plucking of the blighted portions of bushes might mitigate the evil; and I would suggest that this message be sent to newspapers and published in the *Gazette*, for general information."

The agents and owners of tea-estates had always attached the greatest importance to the discovery of the eggs, as they hoped by the destruction of these to effect the extermination of the pest, or at least a diminution of its numbers and with the view of assisting the planters in finding out in what part of the plant the eggs were deposited, long before I visited Assam, I had suggested that eggs or viviparously produced young should be sought on the young and tender shoots. Some time before my mission was arranged, I received from Mr. Alexander Wilson several microscopic slides, which that gentleman informed me, were supposed to contain viviparously produced young taken from young shoots by one of his employés, who, I think it was stated, had actually witnessed their birth on the shoots.

These slides proved on examination to contain ripe eggs, which had evidently been taken from the bodies of females and not from the plants at all—the preparer of them having evidently mistaken the two unequal processes which spring from the mouth of each egg for antennæ, and hence jumped to the conclusion that he had found fully-formed embryos ready to be deposited alive upon the bushes. Though I never succeeded in finding embryos in eggs extracted from the bodies of females, it is possible, but highly improbable, that under certain circumstances such may occur, that eggs may be retained by the females until development so far advanced, and be inserted in this condition in the usual manner into the substance of young shoots just as undeveloped eggs are.

The knobbed ends and also the sides of the two tubular processes of the mouth of the egg-shell, to a greater or less extent, are studded with button-shaped elevations, each of which has a minute pit in its centre. These pits are probably the ends of minute tubules which place the lumens of the processes in direct communication with the exterior, and thus serve to carry air to the developing ovum. The eggs are provided with deep saucer-shaped lids, perforated, sieve-like, with holes which are large enough to admit spermatozoa.

I placed four or five virgin females in company with males, in a cage with fresh tea shoots. I witnessed the union of the sexes, and the subsequent deposition of the eggs. As soon as the eggs were laid, I dissected one of them out of the shoot, and mounted it in glycerine and water. On crushing the preparation by slight pressure of the covering glass, the contents of the unsegmented ovum ran out together with four spermatozoa. I still possess this preparation, which is proved to have been made from an egg taken from a shoot, by the presence of masses of the tissues of the plant containing spiral vessels. The respiratory processes of the egg shell so closely resemble the fine pubescence which clothes the surface of the shoots as to be quite indistinguishable from it to the unaided eye, to eyes unaccustomed to zoological work, even with the aid of an ordinary lens; so that it is no wonder that the planters had altogether failed to find the eggs of this pest, after these had left the bodies of the females.

In order that the reader may form some idea of the numbers of the eggs, I may state that on one occasion I counted more than forty eggs in twelve shoots taken consecutively and at random, from a plucker's basket, and that on another occasion I selected and plucked from one bush of a plot of tea, which was only moderately blighted, four shoots with one or more eggs in each. The females appear instinctively to avoid puncturing the shoots or the parts of the shoots in which they lay their eggs, for one can rarely find eggs on badly injured shoots.

Each of these pests stands to the plant in the relation of parasite to host, and the plants effected may be considered to be suffering from parasitic disease.

After an exhaustive examination of every case, in which the quality of the soil, or shade or "want of cultivation," and the bug-disease seemed to be connected as cause and effect, I have arrived at the conclusion that neither of these separately, nor all three in combination, can be considered to be the cause of, although they may when combined possibly promote, the disease.

Many animals are protected from the attacks of their enemies by their nauseous flavour or odours, or by both, and their enemies recognize them by their odour, or, in default of this, and after experience of their flavour, by their colours, and hence avoid them. Why should there not be similar protective odours and flavours in plants? Mr Wood-Mason then goes on to indulge in speculations, at which we suspect most planters will smile, to the effect that the tea bug chiefly affects China bushes, because of the mild flavour of this kind, while they are deterred from attacking the indigenous Assam because of the "*rasping*" flavour of the infusion yielded by its leaves! In all our reading of the literature of Indian tea, we certainly never understood that pure indigenous Assam tea was more exempt from the "blight" than China bushes, but Mr. Wood-Mason's very positive assertion, if it can be substantiated, deserves special attention. He writes :—

The species which affords the strong and rasping liquor when pure, enjoys an almost complete immunity from attack; but the species which affords the milder liquor suffers most severely. I have no doubt that the more powerful juices of the indigenous tree serve to protect it from its enemies, and that the milder juice of the Chinese bush render it liable to attack. The question arises, how do the bugs distinguish between the two? By their olfactory organs just as other insects distinguish

different but closely similar plants, infallibly selecting the right food-plant for their larvæ. It by no means follows that because we are unable to distinguish two different plants by their colours, insects cannot: just as there are sounds inaudible to human ears, so there must be odours imperceptible to human noses: "when," as Mr. Darwin has remarked, "man can perceive no change in plants or animals which have been exposed to a new climate or to different treatment, insects can sometimes perceive a marked change. The same species of cactus has been carried to India from Canton, Manilla, Mauritius, and from the hot-houses of Kew, and there is likewise a so-called native kind, formerly introduced from South America, All these plants are alike in appearance, but the cochineal insect flourishes only on the native kind, on which it thrives prodigiously." Humbolt remarks that white men "born in the torrid zone walk barefoot with impunity in the same apartment where a European, recently landed, is exposed to the attacks of the pulex penetrans." This insect, the too well-known Chigoe, must therefore be able to distinguish what the most delicate chemical analysis fails to distinguish, namely, a difference between the blood or tissues of a European and those of a white man born in the country. But the discernment of the Chigoe is not so surprising as it at first appears; for, according to Liebig, the blood of men with different complexions, though inhabiting the same country, emit a different odour. When it is remembered that amongst different but closely allied species of animals some are nauseous to the taste and malodorous, while others are the reverse, and the plants that naturally possess a powerful active principle, may, when placed under new and different climatal conditions, wholly lose that active principle, it will not be considered surprising that two species of plants which, like the indigenous and Chinese tea-plants, have been produced under such totally distinct conditions, and diverge from one another in so many important morphological characters, should differ also in chemical quality of their juices.

The speculation is most interesting and ingenious, but the question arises, is it correct? Let Indian tea planters say. For other reasons than susceptibility to blight, the propagation of China tea in India has long been abandoned in favour of Assam indigenous or hybrids as closely approaching Assam as possible, but, we have never until now seen it stated that the bug, when it visited a tea district made any such distinction as Mr. Wood-Mason so confidently affirms. If Mr. Peal, who is still living and still adding to the stores of useful knowledge connected with tea, confirms what Mr. Wood-Mason states, we shall be surprised but satisfied. At present we strongly doubt, and we regard Mr. Wood-Mason's discovery as to the mode in which the eggs are deposited as the most valuble part of his book.

The *Indian Agriculturist* quotes somewhat more largely regarding the "red spider" mite than did the *Englishman*. We copy as follows:—

The mites lay their eggs in hollows, close to the ribs of the leaves usually. The eggs are oblate spheroids, flatter at one pole, by which they are firmly and broadly attached to the leaves, than, at the other, at which their transparent shell is suddenly drawn out into a long and tapering and slightly curled glassy process. They are red, like the mite itself, and at the close of sigmentation present at their surface a beautiful reticulated patteru, due to the presence of a concentrated and dark-coloured layer of protoplsam around the nuclei of all the cells of the blastoderm. The young arachnids leave the egg as six-footed larvæ, which do not attach themselves as parasites to the bodies of insects and spiders, as do their distant relations the Trombidiidæ, nor undergo any of those strange changes which many other mites pass through in the course of their development, but attain to the adult condition by a simple change of skin, that usually, though not perhaps invariably, is made on the same leaf as that on which they emerged as larvæ from the egg. The shells of the hatched eggs, remain glued to the leaf for some time as microscopically small objects resembling saucers.

Preparatory to the final moult the mites draw all their legs in under them, become perfectly motionless, and appear to change from red to white; but no change of colour actually occurs, the appearance of whiteness which the thin and colourless old skin present being due to the access of air to the interval between it and the new.

The male differs from the female not only in size but also remarkably in the form of the body. The former sex is the smaller and in the shape of the body resembles a plover's egg, being broadly rounded at the anterior end and pointed posteriorly while the latter resembles an egg which is similar an semi-circular in outline and nearly equal at both ends.

The mode of reproduction is described, and the manner in which the juices are sucked from the leaves was shown in our extracts from the *Englishman*. We quote the following description:—

The tea-mite is an excessively minute animal, the female measuring only about one-twenty-fifth of an inch, or about one milimetre in length between the extremities of the outstretched anterior and posterior groups of legs and the male being about one-sixth smaller. The egg shaped body is divided, except when inflated to its fullest extent by imbibed tea-juices, by distinct grooves into six divisions in the female and into seven in the male; and each of these divisions, as to which it is exceedingly doubtful whether they represent true segments, bears two pairs of long and stiff and backwardly directed white hairs, forming four longitudinal series placed two on each outer third of the upper surface; the first segment, which has only one pair of hairs, and is moreover, longer in the male than in the female, carries, in both sexes, two groups of two unequal eyes, forming two pairs, one of which, the anterior, is smaller than the other.

To the naked eye the tea-mite appears as a dull blood-red speck, but under the microscope presents itself as a much brighter and more variously coloured object, its legs being of a pale flesh-colour adorned with a light crimson stripe, the front segment of the body bright crimson, with semi-circular mark in the middle of its hinder margin, concolorous and in contact with the deep blood-red of all the remaining segments in the female (which is dark blood-red from the front end of the second segment to the extremity of the body), but of the four following segments only in the male, which has the two terminal segments bright crimson, like the front of the body. The legs are sparingly clothed with long and colourless hairs, and they are all terminated on each side by one or two curved bristles, and in the middle by a single hooked claw, on either side of which there spring from the apex of the terminal joint of every limb two delicate glossy threads with enlarged tips forming long and thin stalked suckers, by the aid of which the mites are enabled to retain their footing and walk securely over the leaves, and the males to clasp the females firmly by the back during copulation. In crushed specimens which has been rendered transparent by re-agents, a pair of highly refractive and spheroidal solid bodies having a faint concentric structure was always to be made out beneath the skin in front of and internal to the eyes, in a position, therefore, corresponding as closely as possible with that in which Claparede never failed to find in embryos, but only in embryos, of *T. telarius*, a pair of sacs each containing a pear-shaped solid body.

I propose for the tea-mite, which would appear to be unknown to science, the name of *Tetranychus bioculatus*, in allusion to its double (really two pairs of) eyes.

We cannot help thinking, that, apart from collecting and destroying affected twigs and leaves, as well as the insects themselves and their eggs, the most successful remedy is likely to be that which has answered in the case of the *phylloxera* eggs on vines, viz., a mixture of oil (coconut, or probably better still, castor?), kerosene, quicklime and water.

As *helopeltis* generally confines itself at first to isolated trees or, small patches in the case of tea, it ought to be pretty easily reached and eradicated.

VARIOUS PRODUCTS IN CEYLON.

12,000 RUPEES FROM FOUR ACRES OF CARDAMOMS—NEW COMPANIES CONNECTED WITH CEYLON—ESTATES RISING IN VALUE—THEFT OF TEA LEAF NOT A PAYING SPECULATION—MORE THAN ENOUGH OF RAIN—OUTTURN OF COFFEE IN COLOMBO.

Let me chronicle the best I have heard that cardamoms have done. Four acres produced in one year the princely sum of twelve thousand rupees. I write it out in full, rather than put it in figures, for it would appear only reasonable to any ordinary proof reader to delete a cypher, and, even then, think the thing not more than presentable. All the same, I have no reason to doubt the correctness of the sum stated, or question the veracity of my informant.

We are soon likely to have more Companies started with Ceylon as the field of their operations. A member of one of the Colombo firms went home a little while ago at the call of some Glasgow capitalist, with the intention of promoting a Company for the cultivation of tea, and there is another gentleman at present flying about the country trying to buy up estates for a new Company which he is keeping dark. He wants them cheap, and he is likely to get them.

Nevertheless, those that have a good thing hang on to it: witness a Matale estate of the Lanka Company which they now value at three times the amount they paid for it, so well is the cacao growing there. An estate in the Hantane district which changed hands this year is likely to cover the price paid for it by its coffee crop alone. Anyhow, if that does not do it, the cinchona bark will easily make up the difference.

My critic "Ex Nihilo Nihil Fit," in your issue of the 24th ultimo, has, I think, got himself into a state of quite unnecessary alarm regarding the effects of the natives going in for tea. If he were to consider for a moment what a cooly picking tea can manage to bring in for a day's task, working ten hours, he will see at once that the old game of reaping where another has sown, endeared although it be to the native mind by many a sweet association, won't work in a tea garden. I suppose that 16 lb. of green leaf per cooly is a very good average, taking all the year round; some indeed can't work up to this, and the value of that at a tea factory will be at 10 cents a pound the munificent sum of R1·60. This too, remember, the result of *ten hours'* work, and under the most favourable circumstances. How different therefore must be the returns of tea stealing as compared with that of coffee stealing. Among heavily bearing coffee trees a thief might fill a sack in an hour's time, stripping ripe and green as he goes, and its value would be, even in these days of ruinous prices, five times as much as the value of the green leaf gathered by a cooly in a day. You can't strip tea in this way. My critic must try again, and think of some other reason why the native should not grow it: the fear of having raids into his garden is unfounded, and his alarm is unreasonable. Appuhami is willing to risk something when he is out on the prowl, but I think he is likely to try everything else before he turns his ingenious mind to tea stripping.

The weather is trying to make up for the lack of rain we formerly suffered from, for now we have more than enough of it. Every afternoon it deluges us, trys our drains, washes our roads, leaks in at the roofs of our bungalows and now and again stops work. This afternoon, in an hour-and-a-half, 3·16 was registered. Not bad that: only when it comes down in that way it has changed its character somewhat from the beneficent to the destructive, and you would rather see less than more of it.

Coffee is turning out shockingly bad in Colombo, and when that is added to the low prices it is very unfortunate. Chetty estate and garden parchment is taking from 6 to 7 bushels to the cwt., and estate coffee which used to average considerably under 5·00 is taking from 5·25 to near 6·00. There is no use crying out: you see the untoward state of things ere the coffee leaves your store, but all the same it is deplorable, and takes a good deal of the heart out of working.

PEPPER CORN.

DR. TRIMEN ON *HELOPELTIS*.

The letter we have received from Dr. Trimen on the subject of *Helopeltis Antonii* is reassuring, inasmuch as the Director of the Royal Botanical Gardens states that an insect indigenous to the country is less likely to do great and widespread mischief than one recently introduced. Still we must vigilantly watch this new enemy to the planters, which, we trust, may not find our tea to its taste. There can be no question that the most effectual remedy lies in the destruction of the eggs. If Signoret's paper in its integrity is not in the island, we should think that, at least, in recent editions of Kirby & Spence and Westwood, or similar works, there may be references to it, including, what would be specially interesting, an account of the source whence the French naturalist received his specimens. If any possessor of books on entomology finds the desiderated information, we hope he will communicate it to the press.

We greatly regret the misprints to which Dr. Trimen refers, but the only way to prevent such errors in a country like this, (where compositors can only do their best and editors are not scientists) is carefully to write proper and scientific names in clear print hand. What with Dr. Trimen's local researches and the publications of Messrs. Van Gorkom, Moens, Peal and Wood-Mason, we are by this time pretty familiar with the life history and habits of *Helopeltis Antonii*. Our business now is to wage such incessant war against this destructive insect that ere long it may be difficult to procure a specimen even for scientific purposes. With weather such as we are at present experiencing, the pest is more likely to decrease than increase.

We append Dr. Trimen's letter:—

THE EGGS OF HELOPELTIS.

To the Editor of the Ceylon Observer.

Royal Botanic Gardens, Peradeniya, 6th Nov. 1884.

SIR,—In a letter signed "B" from South India inserted in your paper of 25th October was a question as to the size of the egg of *Helopeltis*, which I see I am asked to answer. This is easily done. The eggs are by no means "microscopic" as you suggest, but, as I stated in my report (par. 5), large for the size of the insect; in fact, they are fully 1-24th inch long and in *themselves* by no means inconspicuous, though so carefully concealed.

The extracts from Mr. Wood-Mason's treatise on *Helopeltis* in Assam which you have lately reprinted from Indian papers are of much interest. I have not had an opportunity of seeing this book as yet. Mr. Wood-Mason's description of the eggs agree with my own above referred to, as also that of their position in the young shoot. These points are not novel, being only confirmatory of Van Gorkom's observations on Cinchona in Java. The proceedings of *Helopeltis* are clearly identical on Cinchona, Cacao, and Tea, and what I have stated with reference to Cacao applies *mutatis mutandis* to the other plants. From the observation of only two eggs *in situ* I did not like—having no pretensions to any entomological knowledge or training—to generalize as to their position in the shoots, but in par. 12 I recommended the removal of the latter in cases where the presence of the eggs could be detected; it is to be hoped that Mr. Wood-Mason gives some help as to how this is to be done.

I may add that the eggs observed by "B" in a slit in the bark are not those of *Helopeltis*, but of some Orthopterous insect (Locust or Grasshopper) the females of which possess large sabre-like blades to the ovipositors.

When writing my report, I had no opportunity

of referring to Signoret's paper * (which is in the annals of the French Entomological Society) containing the original description of *Helopeltis*. I do not suppose that paper is in Ceylon. That the insect should prove to be native to the island is perhaps on the whole a matter for satisfaction; as experience teaches us that organisms which have in course of time established a balance with their surroundings in nature have less opportunity for sudden and great increase in numbers than is the case with many introduced species which find their new environment to be in their favour. But, no doubt, our cultural operations do much to upset or modify the easily influenced equilibrium which has resulted from ages of a complicated strife.—I am, sir, your obedient servant,

HENRY TRIMEN.

EARNINGS OF INDIAN TEA COMPANIES.

A list of twenty-three Companies has been published by Mr. Ernest Tye, the aggregate capital of which is £2,483,907; total acreage 42,355; average capital per acre £58; total crop 13,177,522 lb.; average yield per mature acre 311 lb.; average cost per lb. 1s: average value per lb. 1s 3d; profit per acre ranging from nil to £9-3-7; average dividend 5 per cent. In seven cases, however, there was no dividend, while as regards the rest the dividends ranged from ½ per cent to 14 per cent. The capital per acre ranged from £25 to £100, £116, £117, and even £143! Of course it is not likely that on an expenditure of £143 per acre a dividend will ever be received. The table is of permanent interest to Tea planters and will be embodied in full in the *Tropical Agriculturist*.

SUGAR: PRODUCTION AND CONSUMPTION.

The discussion over "bounty-fed sugar" and the West Indian grievances has drawn forth a report from Mr. Giffen of the Board of Trade, which puts in a striking way, the extraordinary progress of the sugar trade:—

The production and consumption of sugar have increased enormously in the last 30 years. According to Messrs. Rueb and Ledeboer, who omit certain outlying countries, such as India and China, the increase in production in the countries they enumerate is from 1,423,000 tons in 1853-55 to 3,564,000 tons in 1880-82, and to over 4,000,000 tons at the present time. The increase in each decade over the previous one is 30 per cent, and the amount of the increase has consequently also increased, the annual production in the whole of the British West Indies and British Guiana in 1877-79 was 5,200,000 cwt.; in 1880-82 it was 5,546,000 cwt.; and in 1883, 5,892,000 cwt., equal to 260,000, 277,000, and 295,000 tons. In recent years the beet-producing country which has advanced most is Germany, the increase being from 569,000 tons in 1880-81 to 840,000 tons in 1883-84. Austria-Hungary, which formerly was most complained of in the matter of bounties has declined in the same period from 498,000 to 415,000 tons. In France, which is not alleged to have given bounties on production in the interval, there is an increase from 333,000 to 425,000 tons. The consumption of sugar in the United Kingdom has now reached the enormous total of 1,083,000 tons, equal to 68 lb. per head of the population. This represents an annual expenditure by the people of the United Kingdom on the article amounting to £30,000,000, or about half the amount spent on bread when the wholesale price of wheat is under 40s per quarter. The consumption has increased from 15 lb. per head in 1840, and the article from being one of luxury has become a material part of the food of the people, its magnitude being appreciable even when compared with wheat. It is a fallacy to represent all beet sugar as bounty-fed, and to ascribe the increase in beet production exclusively to bounties. The bounty being on the export only, the *maximum* quantity of beet sugar receiving bounties cannot be more than the exports from the bounty-giving countries, Austria, Germany, and Belgium, amounting to 700,000 tons, or about 16 per cent out of a total production, according to Messrs. Rueb and Ledeboer, of 4,200,000 tons, and about 11½ per cent of the absolute total production of 6,000,000 tons. If it is argued that all beet is more or less stimulated by the bounty, then a bounty of £3 per ton, calculated on 700,000 tons, would amount to £1 per ton only on 2,000,000 tons, the total beet production, and would be too insignificant to have the effects alleged. There is no pretence for saying that if the incubus of bounties were removed natural sources would not at once be developed to supply any void caused by the diminution of bounty-fed production.

* The abbreviation "Sgnt." for this writer was misprinted "Lynt." in my report (par. 3) as given in *Tropical Agriculturist* for Oct. (p. 328) where also *Capsidae* is given *Cuspide*. [We shall note these for errata.—ED.]

HOME PAPERS ON PLANTING NEWS:

PHYLLOXERA—QUININE SYNDICATE—BRITISH HONDURAS—INDIARUBBER—COFFEE CONSUMPTION AND NEW FIELDS.

We have to acknowledge the receipt of the following "exchanges" from which we shall quote fully into the *Tropical Agriculturist*:—"Gardener's Chronicle" under date Oct. 16th; "Field," Oct. 11th; "Pharmaceutical Journal," Oct. 17th; "Society of Arts Journal," of Oct. 17th, which has an interesting article in the "Pine Forests of North Carolina"—forests which in their sombre dreariness and monotony we found to extend with but few breaks along the eastern railway route through both North and South Carolina, part of Georgia and even into Florida; "Journal of Horticulture," of Oct. 16th; "Nature," of Oct. 16th, from which we learn that Messrs. Spon have in the press "an Electrical Supplement" to Mr. Molesworth's well-known "Pocket Book of Engineering Formulæ"; and from which we take the following piece of news:—"Phylloxera is making steady progress in the Rhenish vineyards it seems. The pernicious insect has now been found on the right bank of the river, in the vineyards of Castle Ockenfels near Linz, where over 100 acres are infected. State aid has been asked for at Berlin, as the occurrence of the pest near Linz is far more serious than that in the Ahr Valley."

"The Chemist and Druggist" of Oct. 15th has some curious information about Kola-nuts and from which we learn of a new "Quinine Syndicate" as follows:—

"QUININE SYNDICATE,—Objects: To purchase and prepare the cinchona bark, and to carry on the business of quinine manufacturers. Capital 1,500*l*., in 10*l*. shares. Signataries: S. Howard, 35, Queen Victoria Street, 1 share; S. Grady, Dashwood House, 25; W. Tryett, 32 Great St. Helen's, 25; P. M'Fadzen, Madras, 25; H. B. Arbuthnot, 33, Great St. Helen's, 25; A. C. Walters, 44, Elm Park Gardens, 1; S. Jennings, Westbury House, Denmark Hill, 1. Registered without articles of association by Ochme and Summerbeys, 167 Gresham House."

The *Field* of October 11th has a long paper on British Honduras by "Alice de le Plongleon" from which we quote a paragraph referring to the good work done by the late Governor, better known when Mr. F. Barlee as the energetic Colonial Secretary of Western Australia where we saw evidences of his energy in 1875:—

His endeavours to develop the fruit trade having proved very successful, Sir F. Barlee obtained a contract from Messrs Mackeea, of New Orleans, for more frequent steam communication with the United States, with the result that, in 1881, no less than seventy-eight steamers had been to Belize, instead of one steamer a month as formerly, and that a 500-ton steamer could come every two weeks and find a full cargo of fruit.

One of the last things done in Belize by order of the late Governor nearly created a revolution, in spite of its wisdom. The burial ground was not a great distance from Government House, and, as the sandy soil was quite shallow, the graves could never be dug as deep as is desirable for the health of a community, so that the remains were often submerged by the water, which is in many places near the surface. The consequence of this was that, when the wind blew from the south, very offensive odours were wafted into Regent-street. To obviate this unhealthy nuisance, brick vaults were made, in which every body

was ordered to be deposited; but the negroes wanted to be buried in the sand, and indignantly protested against these receptacles.

"The India Rubber, Gutta Percha and Electrical Trades Journal" is the latest of the technical monthlies sent to us in exchange for the T. A. It contains some valuable information, more especially a series of papers on "the collection and preparation of India-rubber" from which we shall quote freely into our own monthly periodical for the benefit of rubber planters. "The Indian Mercury," which is published in London in the interests of Java readers more especially, mentions that

"The decline in the use of coffee in England" was the subject of a lecture delivered before the Glasgow Philosophical Society recently by Dr. Wallace. The lecturer directed attention to the anomalous position coffee occupied as compared with alcoholic liquors, tea, and cocoa. While the consumption of spirits, wine, tobacco, tea and cocoa had increased, that of coffee he said, had decreased to a very considerable extent. In his opinion, the people of this country were losing their taste for coffee because they could not get it in a pure state. When the consumption of coffee was at its maximum, chicory was mixed with it. The abuse of coffee was now so universal that very few people really knew the taste of pure coffee. When visiting France or Belgium the Briton enjoyed his office, because he got it in a pure state. Besides chicory, coffee was often mixed with burned sugar, dried figs, date stones, decayed ship's biscuits, beans, peas, and dried roots of various kinds, including turnip and beet. If the Government would absolutely forbid the sale of coffee mixed with any other ingredient, he felt sure that the beverage would soon regain the high reputation it had previously enjoyed. A discussion followed in which the speakers unanimously agreed with the views enunciated by Dr. Wallace.

Of more immediate interest to coffee planters is a telegram in the London *Times*, dated Brussels Oct. 5th:—

The *Mouvement Géographique* states that near the station of Loukolela, on the Congo, a tract of about a hectare has been found covered with wild coffee trees. Dr. Chavanne has also pointed out certain territories on the Congo which appear to be especially fitted for coffee plantations.

TEA IN SOUTHERN INDIA.—Says the South of India paper:—"We see that the *Ceylon Observer* wishes to know if red spider is ever *seen* on our tea bushes; we can truly say it has been, though not very destructive in our cold climate. The same may be said of the scale on some China trees, we have seen it very bad indeed, but it is one of those pests that come and go. As for porcupines not touching the China plant, our experience teaches that neither China nor hybrid is safe from their ravages."—*Indian Agriculturist.*

HOW TEA SUCCEEDS IN CEYLON: DIMBULA, 20th Oct.—Bravo! I say for that article of Friday last on "Tea Culture and its Profits in Ceylon.' Who, after reading that article with its positive facts to bear it out, could for one moment doubt the successful culture of tea being an established fact. All the products hitherto tried in Ceylon have more or less proved themselves eccentric in their tastes of soil elevation, temperature, rainfall and a hundred different eccentricities, and in addition to them to have something very disagreeable in their nature judging from their numerous enemies. How different is the tea bush: high and low, hot and cold, dry and wet, all conditions seem congenial to it; and, as regards enemies, so far as we have yet seen, it only laughs at them. It reminds us rather of the sturdy weed or the hardy jungle stuffs which, as soon as we have abandoned the delicate coffee or cinchona in despair, take their place and grow with a vigor (quite unaided) which is maddening to behold after treating the coffee, cinchona, cacao, &c., with all the care and kindness which science tells us they require and spending our rupees in providing them therewith. As an instance of the hardiness of tea, I know of a block of land at about the same elevation as Abbotsford, which was planted with coffee and cinchona, but soon the unfortunate proprietor saw it was too cold for the former and something in the soil unsuited to the fastidious taste of the latter, so he decided to abandon, but before doing so planted fifty acres with tea seed at stake. This was two years ago. So, having to find work for his coolies on an adjoining estate the other day, he put them on to clear up the fifty acres. What was his surprize, to find the tea bushes holding their own among the weeds and jungle stuff! and though, perhaps, not so high as they would have been in open ground were *per, contra* more "bushy." The height was from two to six feet. On the face of the data given by you and this one in addition, what encouragment there is for capitalists to come, but come soon they must, for as you hint, it won't be long till if they wish to invest in land for tea they will have to pay ten times the present price for it.

OUR TEA INDUSTRY.—The growing interest which is taken in commercial circles at home in the Ceylon Tea enterprise may be illustrated by the arrival on a visit to the island of a member of the well-known Mincing Lane House of Messrs. Wm. J. & Hy. Thompson, so prominently connected with the great tea import trade of the Metropolis. Mr. Arthur Thompson has but a short time to spare from the pressure of business; but Ceylon is so happily situated in its mail-steamer connection and its good internal lines of communication that a very fair idea of our tea districts can be obtained in a few weeks. A busy "city" merchant escaping some of the worst of the winter weather (including the "November fogs") in London, can make the voyage out, see what is going on here in all the principal groups of districts in the planting, manufacturing and shipping of tea, and return home all within a holiday trip of three months. This cannot be done in respect either of the China or Indian tea districts, nor, even if time were no object, can the same comfort and enjoyment be got out of the trip to Assam or China, we think. For with the scenery of Ceylon, no English visitor is ever disappointed. It is unfortunate for Mr. Thompson perhaps that our north-east monsoon should now be on, the best time to arrive here being from 1st December onwards; but we trust such breaks in the weather may be experienced as may enable the country to be seen to advantage. During four or five weeks Mr. Thompson will probably be able to run round the principal districts, and we feel sure that no pains will be spared to enable so competent a visitor to form a sound judgment of the present position and future prospects of tea planting in Ceylon. The difficulty will not be to find opportunities, but for Mr. Thompson to find the time to visit all the places where his presence will be bespoken and heartily welcomed. It is encouraging to know that Mr. Thompson, who knows so much about Assam and China teas, comes favourably impressed with the future for Ceylon teas, and we trust this prepossession may be fully confirmed after a month's local observation.—Not simply tea, however, but coffee and cinnamon especially, and other products to a less degree, will receive the attention of the gentleman whose presence amongst us we have thus ventured to allude to. Mr. and Mrs. Thompson start for the Central Province tomorrow, and that their visit may be a thoroughly enjoyable one will, we feel sure, be the wish of all interested in the future of our planting industries.

THE INSECTS referred to in last night's issue having been submitted to the gentleman who is good enough to help us in matters entomological, the following is his report :—

"The large bug belongs to the family *Reduviidæ* They are pre-eminently insectivorous and are usually scentless The smaller bug is not *Helopeltis*, but somewhat resembles it. The beetle belongs to the family *Melolonthidæ*. It is a small chafer often found on rose trees, feeding on the roses."

"THE ARGONAUTIC EXPEDITION TO PERAK."—Messrs. G. H. D. Elphinstone and A. H. Thomas have safely returned from their expedition to Perak, and we are glad to learn from Mr. Elphinstone that he is well satisfied with the result of his visit of inspection. He visited sugar plantations in Province Wellesley to find as great depression prevailing (in reference to their product) as anywhere in Ceylon. The "Klings" everywhere encountered, turned out in many cases to be old Ceylon coolies, some of whom recognized their old durais. Not only in respect of Tamil coolies, but also of planters and other residents did the visitors feel as if they were in an outlying province of Ceylon. Every second man met had been in this island or had relatives here. As might be expected "Logie" was not content with a mere perfunctory visit, but, as he was about it, went thoroughly into the business of tin exploring and mining, receiving the assurance in return from an experienced responsible Chinaman that no European had ever before spent so much time with him or enquired so closely into the practical working, although many had come and invested their money ! No wonder, though such investors have in too many cases reaped little or nothing. Mr. Elphinstone was well pleased with the 200 acres of land allotted free to his party. It is situated at the junction of two rivers on flattish land within eight miles of the sea, and promises well for tin. He returns again in three months or so. He visited the Waterloo plantation of Government now under the care of Mr. J. F. Cock, formerly of Matale, where Liberian coffee and cacao are growing well : but, of course, the coffee fungus is present. The difference between our hillcountry and that of Perak that arrested attention most was the absence in the latter of such cliffs as those of Gallaha, Wattegodde, &c., with disintegrated rock and soil below. In the Straits the precipices seem to be all perpendicular, granite with a good deal of slate. Mr. Elphinstone describes the conditions of successful boring for tin in Perak as follows :—First stratum, leaf-mould ; second, gravel ; third, light-blue clay and white quartz and precious stones ; then the tin-wash lying on dark-blue clay. The point now is whether tin can, under similar conditions, be profitably worked in Ceylon. Gygax in his Report on the Geology and Mineralogy of the Sabaragamua district, written in 1847, had the following :—

"*Tin.*—The tin ores are also found in the alluvium just below the strata of precious stones. The locality most favourable for the existence of tin is decidedly in the eastern side of the district along the base of the high mountain zone, and especially near the Edelgas-iua Pass. To work tin mines here with success, it will be necessary, I anticipate, either to reduce the height of the rivers or to employ powerful pumps in each mine, so plentiful is the water and at so high a level. The position in which this ore has been met with is precisely similar to that of the ore in Saxony and Siberia, with tourmaline, white topaz, zircon, garnet, and corundum."

Between Balangoda and Haldummulla at the foot of the hills would be the place to explore for "tin," the very name of which sounds attractive in these hard times ! But we suspect it had better be sought by means of a tea-garden rather than a tin mine—in Ceylon at least.

JAVA TEAS are Improving. No. 1 Pekoe of one Java estate by this mail sold higher (2s 11½d) than any of the Indian, while for ordinary teas the prices got were very good. Messrs. White & Co. surmise that some of these good teas must have been plucked from plants grown from Assam seed.

MR. GASS, Deputy Conservator of Forests, who was for some time acting for Colonel Jago, has, we learn, been presented by the local Government, with the gold medal awarded to it for the Cinchona collection exhibited at the Amsterdam Exhibition.—*South of India Observer.*

MR. C. H. DE SOYSA, the well-known Sinhalese capitalist, is, we are glad to hear, about to plant tea on an extensive scale on some of his lowcountry properties. Mr. De Soysa has already put some tea on Charley Valley plantation, Maturata, and we have no doubt this will be followed ere long by operations in Hewaheta, Maskeliya, and other districts where this enterprising gentleman has land.

SALE OF ST. ANDREW'S ESTATE, KALUTARA.—Messrs. Somerville & Co. sold the above estate to Mr. E. Schrader for R1,300, at public sale as advertized. The estate consists of 74 acres, more or less, of nutmegs 1 to 2 years old ; 9 acres, more or less, of arecanuts, 2 years old ; 11 acres, more or less, of coconuts 1 to 2 years old ; 16 acres, more or less, of cardamoms, mangosteen, pines, jack and cotton trees ; 16 acres, more or less, jungle, &c. ; total 126 acres.—Local "Times."

OBITUARY.—Many of our planting friends will read with much sorrow and regret of the death of Mr. John Jackson, at one time Manager of the Scottish Assam Tea Company, and subsequently partner with his brother in the well known firm of Messrs. W. & J. Jackson. A few years ago Mr. Jackson settled down in America, and was there engaged in establishing a tea business when the unexpected news has reached us of death—from fever. Mr. Jackson was very highly esteemed by all who knew him.—*Indiyo and Tea Planters' Gazette.*

ANURADHAPURA, 18th Oct.—From the 11th October instant we are having rain daily. It has cheered the heart of the cultivator and of the land-owner. More land than was ever anticipated by us has been brought under cultivation, during the last two months. Here too the labour will have to be imported from India in a year or so. The Sinhalese *goiyas* are capital hands, no doubt, in clearing jungle, but they are not as hard-working as the Indian coolies. Messrs. Valupulle, and Perumangaar, the two Jaffna gentlemen called the pioneers of paddy cultivation hereand who have bought lands extensively, imported Jaffna labour at a heavy cost. If the Yoda Ela work be not finished before the end of 1885, the Government will not be in a position to give *sufficient* water to the lands that are now being brought under paddy cultivation. It appears people do not generally understand the advantage of buying lands for cultivation here. For the benefit of all who may like to know, I will give a short account of how matters stand. Though what I write here has come under my personal observation, still I will put it in a hypothetical form. If an acre of land be bought for R50 (this is the maximum price realized for the best plot of land) ¼th of this sum must be deposited at once, the other ¾ths by three instalments. To the capital for the first year (R12·50) must be added for the clearing of jungle and burning it R15 per acre. Sowing, reaping, stacking and threshing anuther R5. The whole cost, including the price paid for the land thus comes to R32·50. An acre of land produces now between 30 and 75 bushels. Taking 50 bushels an acre, and allowing two harvests for the first year, the purchaser has his 100 bushels. Allowing 50 cents per bushel he will get R50 besides the straw and the vegetables, which also may be reckoned at R20 per acre. For a capital of R32·50 the purchaser gets R70. [Oh ! paddy cultivation is not quite such plain sailing.—ED.] What other trade will be surer, safer and more profitable, let speculators decide. The encouragement given by the administrators of this province to the purchasers and cultivators, is another stimulus to intending purchasers to try their fortune here.—"Examiner." [Have 100 bushels of paddy per acre ever been got in Ceylon ?—ED.]

CINCHONA BARK ANALYSIS.—Dr. Paul, the well-known analyst, has issued a circular, stating, that, it having been strongly urged upon him that the present state of the bark trade requires a reduction of the charge for analysis of samples—especially since many parcels are too small to admit of the charge of a guinea and a half—and as it is certain that if such a change were made there would be sufficient increase in the number of analyses to compensate for the reduction, he has decided upon acquiescing in the desire expressed that he should reduce his charge rfo analyses of bark to one guinea each for the future.

CEYLON TEA is thus noticed by a "Peripatetic Planter" of the *Indigo and Tea Planters' Gazette*. I have again visited the Health Exhibition several times of late, and have noticed a decided improvement in both the arrangement of the tea samples on the Indian tea stall, and in the cups of tea provided at the Indian tea refreshment stall. If my letter to you in your issue of 1st July has in any way tended to this improvement, planters in every district save Kaugra have reason to be pleased, as half the stall when I first visited the Exhibition was not only devoted to Kangra, but the printed circulars gave most unfair prominence to Kangra teas. Even now planters from other districts than Kangra might not be *fully* satisfied with the arraugement, but I will not be too critical and am happy to be able to record the great improvement that has taken place. As regards the cups of tea provided, here also there is a notably improvement, perhaps the attendants have learnt their work now. The Ceylon coffee is now excellent, and the Ceylon tea served at the Ceylon stall or bungalow is really very good indeed and far ahead, in point of flavor of the India tea.

WASH AND WEEDS.—"A correspondent, writing to the *Tropical Agriculturist*, brings to notice that in Coorg, on the Sumpajee Ghat, no efforts had been made by planters to save their soil, that hundreds and hundreds of tons had been washed away and then the planters could not understand why there were no crops." Of course, under such circumstances, all the manuring in the world would be useless and this is precisely what has occurred in Ceylon. Clean estates and no provisions for wash are sufficient to ruin any estate. There is but one system for catching, or rather preventing wash, and that is never to weed in June July, and August, but simply to cut over the weeds with grass knives, and keep your pits between every four trees open to catch any wash. A rainfall of fifty inches in a month, such as they have in Coorg, cannot be lightly treated, but demands the most stringent measures. The writer asks if it is not the constant rainfall in Ceylon which causes the cinchona trees to go out. At Neddiwuttum the rainfall is 120 inches and the trees do not go out, because the sob-soil affords drainage; canker has nothing to do with it, it is simply that the roots become poisoned by the water-logged soil, drain it and the trees live.* The cinchona seems to be quite unable to thrust its roots through a stiff clay soil, unlike the Eucalyptus which is stopped by no soil however stiff. The same writer asks, why, if trees are allowed to seed, the bark should be inferior in alkaloids? We know that one year, we took off every blossom from trees on sixty acres of six year old cinchona, and they felt the effects of it for three years, by showing an increased vigour of growth. We should recommend the blossom to be taken off on all occasions, as the trees have then all their efforts directed to making bark instead of seed, and the whole forces of the tree are concentrated upon the leaves and bark. On the same principle we prune a tea tree to prevent flowering and cause all the juices to be concentrated in the young flush. Indeed, to ensure good bark, cinchona trees should be as regularly pruned as tea trees.—*S. I. Observer.*

* No: trenching and draining to the most liberal extent have failed to cause cinchonas to grow on certain patches of soil, while the plants flourished close by. The soil is in such cases at fault, but *why*, the planter has been generally unable to ascertain: Soil which *looked* excellent has failed to grow cinchonas.—ED.

TEA IN THE UNITED STATES.—Three thousand dollars will be expended this year by the Agricultura Department for the cultivation and distribution of the tea plant.—*American Grocer.*

TOBACCO IN BORNEO.—Over two hundred thousand tobacco plants have been put out on the Suan Lamba Estate and planting is going on as quickly as possible. The manager expresses his satisfaction with the experiment so far.—*North Borneo Herald.*

CROP PROSPECTS IN BRAZIL.—*Brado da Lavoura*, S. Paulo. Without doubt our next crop of coffee will be much smaller than any of the preceding three years. Beyond the extraordinary damage to the plantations, some of which were entirely destroyed (*inutilizadas*) by the frosts on 16th and 27th July, it seems that the plantations that escaped these frosts, through the rainfall of the end of June and middle of July produced an extemporaneous bloom, which did not fructify, for the excessive heat of July and August completely destroyed this bloom. Now, the frost bitten trees will produce nothing and those of the other bloom will produce but little, and this only in the spring, and therefore it will infallibily result that the crop will be very small. —*Rio News.*

CURING CARDAMOMS.—In reply to "Naiker's" letter of 19th ultimo, I can inform him that the fruit ought to be dried with the stalk attached, which should be cut off with a scissors when the fruit is dry. He will find that the large quantity of split fruit he complains of, is due to the wasteful and primitive process of picking in vogue in Malabar, viz., picking the mature and immature fruits, at one operation, and also pulling off the raceme instead of cutting the fruit off. Hence the ripe and unripe fruit are equally exposed to the sun, and the fully matured fruit, requiring but very little sun, is split. By judicious picking, the split fruit will not exceed 15 per cent.—COONGICOT.—*Madras Mail.*

COFFEE AND SUGAR FROM CENTRAL AFRICA.—The Rev. Horace Waller recently sent to Mincing Lane samples of coffee and sugar—the first fruits of the Highlands of Central Africa—grown by a young Scotchman a little to the south-east of Lake Nyassa. As the incident is fraught with the greatest importance, the report upon these samples, furnished by Messrs. Patry & Pasteur (whose opinion will, of course, carry all weight), will be of interest to our readers. The sugar, it is believed, was made without the aid of any European machinery. "Both samples," say Messrs. Patry & Pasteur, are remarkably good of their kind, and of qualities which are very current, and would always find a ready sale in London supposing there was a regular supply of them. Both samples reflect much credit on those who, in that distant land (East-Central Africa), have succeeded in growing, and especially in preparing, both the coffee and the sugar for the market. The coffee particularly is remarkable for the depth and brightness of its colour, which gives to it a value probably much greater as a fancy coffee suitable for certain foreign markets than it would possess merely from its strength when roasted; and it compares favourably, for appearance, with the products of European plantations in British India, Ceylon, and Java. It is, however, a rather soft coffee, and not likely to keep its fine colour very long. Indeed, some of the berries are already getting a little faded, with a mottled appearance, which, if it made further progress, would soon detract a good deal from its value in its present state. In all other respects the coffee is as well prepared as possible; it is large, well-picked, and very clean looking, smooth and even, and of bright deep bluish-green colour, and worth in this market about 85s per cwt. in bond. As to the sugar, it is of good grain and colour, good smell and taste, and quite suitable for refining purposes; of a greyish yellow, and equal in colour to the Dutch standards, Nos. 13 to 14. In appearance somewhat like Porto Rico or Barbados sugar. In the present state of depression in the sugar market we cannot put a higher value on it than about 14s to 15s per cwt. We have obtained the opinion of our leading sugar and coffee brokers and dealers on these two samples, and they quite coincide with ours."—*Colonies and India.* [Coffee seems to be indigenous over a large portion of Africa. The latest notice we have seen is of "wild coffee" growing freely at some of Stanley's stations on the Congo.—ED.]

THE TOBACCO CROP just gathered in the United States, has been good alike in quality and quantity. The total acreage is slightly less than in 1883, but the proportion of Havanah seed leaf has greatly increased. From the tobacco-growing states of Ohio, Illinois, and Indiana, the reports are not so favourable. Notwithstanding the excellent supply of tobacco from America, Manilla and other countries, Southern India cheroots are becoming better known and appreciated in England.—*Madras Mail.*

THE PHYLLOXERA AND HELTOPELTIS.—M. Balbiani, Professor at the College de France, was commissioned a short time ago by the Minister of Agriculture to report upon the best mode of destroying the winter eggs of the phylloxera, as it has been found that it is in this way the progress of the parasite is very materially checked. M. Balbiani tried several fresh experiments, among others a mixture of oil, naphtha, quicklime and water. This mixture has been tried upon a very large scale in the vineyards of the Lot-et-Garonne and the Loir-et-Cher, and it possesses, according to M. Balbiani, the double recommendation of being effectual and cheap, as the cost is under a franc for a hundred stocks. [Query? Coconut oil, kerosene, quicklime and water as a remedy for *heltopeltis* and red-spider.—ED.]

CANNED FOODS.—The editor of the *American Grocer* sends us a copy of an article by Brevet Major-General J. P. Hawkins, U. S. Army, on this subject, with a request to give insertion to its main features, in order to allay any distrust which may have arisen in the minds of the public regarding tinned goods, some cases of poisoning having recently been reported. General Hawkins speaks from an experience of 20 years, during which period the U. S. soldiers have used canned foods habitually, and he states that cases of sickness have been exceedingly rare.

CINCHONA.—General Morgan goes out of his way to repeat the time-honoured statement that *Succirubra* will not grow at elevations above 6,000 feet in the district to the west of Ootacamund. I know of at least one large field of matured *Succirubras* (not hybrids) west of Ootacamund, and at a higher elevation than 6,000 feet; and all the *Succirubras* on that large field, not only have grown, but have flourished as luxuriantly as any *Succirubras* I have seen grown at 3,000 feet elevation. Of course this field is not on the crest of a hill or an exposed ridge, but on a slope fairly protected from the south-west winds. How many commonly received statements are founded more upon inference than upon the results of experience!—*Cor., Madras Mail.*

THE POSITION OF QUININE.—The market for both American and foreign quinine remains fairly steady, the only change being a reduction by one American manufacturer, which we announced last week, which has not, however, been followed by a general reduction by other manufacturers. We stated some time since, when the results of the Milan failure first became apparent, that we looked for no speedy advance, and although alone in this opinion the subsequent course of the market has confirmed our views. Quinine at present prices may be considered cheap, and is doubtless good property for the money, but we can expect no early important advance under existing conditions.—*Independent Journal.*

RED BARK TO THE FRONT.—A Colombo merchant gives us information which seems to bear out Mr. Cross's praise of Red Bark, as follows :—"Succirubra bark, which in the early days of planting was rather despised, now seems coming to the front: an analysis that we received by last mail of some renewed shavings off 5 to 6 years old trees on an estate in Udapussellawa (Beckington) were :

Crystallized sulph. of quinine	...		4·36 per cent.
Cinchonidine	...	...	3·30
Cinchonine	...	...	2·40
Total alkaloids	...		10·06 per cent."

The bark was sold for 2s 3d per lb., showing that there is a fair market for a good article.

THE FORESTRY MEDALS AT THE INTERNATIONAL Forestry Exhibition bear, on the one side, a view of Edinburgh from the neighbourhood of Craigleith Quarry, one of the most comprehensive views, carefully and delicately wrought in the die, giving a very fine impression indeed. On the obverse is a wreath of laurel, intended to have the winner's name in the centre, while outside of it is the quaint legend, in relief, 'Be aye stickin' in a tree, it 'll be growen when ye 're sleepin'." The medals have been designed and made by James Crichton and Company, Goldsmiths, 47, George-street, Edinburgh.—*Indian Agriculturist.*

THE FIBRE EXTRACTING EXPERIMENTS.—A Calcutta paper gives the following account of the experiments with Messrs. Death and Ellwood's machine, the invention of Mr. H. C. Smith, on Saturday :—Mr. Death conducted the trial himself, and the result was an unqualified success. The machine which is a very ingenious contrivance, has been successfully used for extracting the fibre from the *moorva* (*sanseviera zeylanica*) from the leaves of the *agave* plant, and from several other leaves; but some doubt was entertained at the outset whether it would answer for the rhea, that is to say, whether, having extracted the fibre, it would leave it in a good condition as regards quality. This, the experiments in England, Paris, and Calcutta, show the machine can do very efficiently. But the main difficulty which had to be overcome was the separation of the bark from the fibre. The outside portion of the bark consists, as those familiar with the plant know, of a film, to which has been applied the term cutose. Below that there is a bark called vasculose, containing the green colouring matter of the plant, and next to that comes the fibre itself. This problem Messrs Death and Ellwood's machine has solved completely. The secret of the success of the machine lies in the fact that one-half of it is, so to speak, water. The machine is worked by steam, the engine employed in the present experiments being a 2½-horse-power one, which, by means of a shaft, could work two sets of machines. The machine itself consists of a cylinder 18 inches in diameter, which is provided with what are called beaters, that is to say, a certain number of projecting ribs, and it revolves in front of the feeding table at a great rate, something like 600 revolutions a minute. The operation goes on in front of the feeding table, and constitutes the entire mechanical portion of the machine, with the exception of the water. Below, and at an angle of about 45°, a strong flattened jet of water passes. The effect of this is, that while the water cylinder is rapidly revolving, and the machine is being fed the beaters catch and break up the stalks into very small pieces and the jet of water coming up from below, meets the fibre, and keeps it up against the beaters, so that it is really beaten in a stream of water. The result is—as Saturday's trial proved to satisfaction—that the fibre is not only cleared of a large portion of its gum, but there is next to no waste, and what little there is can be utilized for several purposes. The waste is used for making blankets. The machine is very easy to work, and any ordinarily intelligent native could learn to work it in a few hours. They are used in Madras, from where some native workmen are daily expected in Calcutta to show that natives can use the machine with facility. The experiment with the rhea plant has proved a complete success, the fibre from 12 seers of stems being extracted in 23 minutes. Rhea is the strongest fibre in nature being two-and-a-half times as strong as the best Russian hemp. It is used to make table-cloths, is an admirable substitute for wool, especially mohair and other lustre wools, and "is far superior even for mixing with silk than jute." —*Pioneer*, Oct. 29th.

BARTUNG.

BY W. T. THISELTON DYER, M.A., C.M.G., F.R.S.

In Dymock's 'Vegetable Materia Medica of Western India' (p. 538) there is the following account of this undetermined drug:—

"*Plantago* sp.? Local name, Bartung.—These are minute, oblong, brown seeds, marked with waved, slightly elevated, longitudinal ridges of a darker colour; one side is arched, the other concave, and marked with a scar showing the attachment to the ovary. They are insipid and have an oily smell when crushed. Soaked in water they become coated with a transparent mucilage. Bartung, usually pronounced Bārhang, is a remedy in great repute in Persia for dysentery. A large quantity is imported into India through Bombay. We have the evidence of Valentine Baker as to its efficacy when he was suffering from the above-mentioned disorder during his travels in Khorasan. When dysentery is supposed by the hakims to be due to a heated condition of the humours, Ispaghul is preferred. When a cold condition is diagnosed, Bartung is given. It is one of the several kinds of Lésán-ul-Hamal described in Arabic works, and is generally attributed to *P. psyllium*."

Early in the year Colonel Beddome, F.L.S., brought to Kew a small sample of the drug which he had received from Persia, where great virtues were attributed to it. At his request we sowed the seed of which it consisted for the purpose of identifying the plant. It turns out to be nothing more or less then *Plantago major*. I have since ascertained that Dr. Forbes Watson in his 'Index to Native and Scientific Names' gives the following identifications of Bartung with various species of *Plantago*:—*P. lanceolata* (Irvine), *P. major* (Honigberger), *P. psyllium* (Birdwood). It might at any rate be worth trying the value of seeds of *Plantago major* in this country in dysenteric affections.—*Pharmaceutical Journal*.

THE CAROB BEAN TREE.

TO THE EDITOR OF THE "AUSTRALASIAN."

Sir,—Your columns from time to time have found space in them to call the attention of your readers to the admirable adaptation the carob tree has for the land we live in. The first special notice of it comes from Adelaide, but in reading a work treating principally of South American (Gaucho) adventures I came upon the accompanying notice of the carob tree, and its publication will, I think, add another illustration of the excellent qualities this tree possesses, and, if planted in Australia, the benefits that would be derived therefrom. J. L. E.

(Copied from *Gaspar the Gaucho*, page 199, "Under the Carob Tree.")

"And their animals also undergo a like rapid recovery from browsing on the leaves and bean-pods of the algarobias—a provender relished by all Pampas horses or horned cattle, and nourishing to both. More than this, the fruit of this vegetable tree, when ripe, is fit food for man himself, and so used in several of the Argentine States. . . . . We can make a meal on the algarobia beans if nothing better is to be had. In some parts where I've travelled they grind them like maize, and bake a very fair sort of bread out of the meal. . . . . These very trees, or others of a similar genus, are the ones whose fruit was eaten by St. John the Baptist. Some think the locusts he ate were the insects of that name, and it may be so, since they are also eaten by Arabs and certain other tribes of Asiatic and African people. But for my part, I believe the beans of the locust tree are meant, which, like this, is a species of acacia that the Arabs call carob, evidently the root from which we take our word algarobia. . . . I do know that algarobia beans are not such bad eating; that is, if properly prepared for it. In the states of Santiago and Tucumau, which are the places I spoke of having travelled through, the people almost live on them—rich and poor, man as well as beast."

A SUPPLEMENTARY PAPER UPON ANTISEPTICS, GERMICIDES AND BACTERIACIDES.

BY WILLIAM CREED.

The object of this additional paper is to keep the mind directed to the bacterian hypothesis of disease, as previously suggested in the *Gardeners' Monthly*, and linked with pear blight and peach yellows. With this recognition in view, I will proceed with a retrospective glance upon a limited number only of long-known and still highly-prized remedies, and which the present generation of investigators consider reliable agents, either as antiseptics, germicides or bacteriacides. Originally it was my intention to have presented a tabulated form of many experiments made by the most renowned men engaged in these valuable researches; this, however, would have taken up too much of your valuable space, so I will substitute it with concise comparisons of the remedies before us, as most worthy of special notice and consideration.

As I am a thorough believer in the prevention of disease, rather than the alternative of allowing disease to "set in" and become uncontrollable, I will first proceed to mention carbolic acid as being probably for many reasons, and in many cases, the ne plus ultra remedy as an antiseptic, and very useful as a germicide and bacteriacide. Antiseptics as such are known by their action in destroying all sources of decay and decomposition, and preventing the formation of germs without acting upon the mineral or vegetable matters present, and their value depends upon their power to prevent the multiplication of bacteria, though this is not necessarily connected with germicide potency; for some re-agents which fail to kill micro-organisms are nevertheless valuable antiseptics. Carbolic acid has been prominently before the public for many years as a successful antagonist to bacterial influence. As far back as 1866-67 I tested this article in a series of experiments upon certain substances of organic origin, and also those of an albuminous nature, the object mainly being to prevent fermentation, decomposition and putrefaction, which are corresponding conditions to the well-known bacterian theory. The intermingling of carbolic acid in the above cases, in proportion of one part to one thousand, was then amply sufficient for the purpose.

In 1868, Dr. F. Crace Calvert, in a lecture before the Society for the Encouragement of National Industry of France, said that carbolic acid was then the hope of the textile manufacturer as an antiseptic in the various glues, sizes, &c., inseparable from this special manufacture, and today we have the very highest authority in stating that it takes the lead for the same purpose, though chloride and sulphate of zinc are valuable and reliable, and frequently used. When we keep in view the fact that thirty-one species of fungi are found growing upon the cotton tissue, and this naturally arising from the use of organic substances, that without the precautionary aid of antiseptics great losses sometimes would be inevitable, why not, then, utilize the same philosophy as a cautionary measure against the spread of bacterian influence upon any vegetable structure to which it may be exposed. Any one having any interest in the matter should secure a proper and effectual syringe or force pump and try the antiseptic principle upon their trees in their own particular districts and at a time at least two weeks previous to any known case of pear blight or peach yellows having been detected, the syringing being repeated occasionally during any anticipated prevalence of the disease.

Dr. Calvert, in his lecture previously mentioned, stated that carbolic acid had the advantage over all other antiseptics, inasmuch that it could not be used for any illegal purpose, as may be the case of corrosive sublimate and some others then on trial; but the well-known investigator and experimenter, Koch, considers corrosive sublimate at the present date the disenfectant and germicide par excellence, as from his own experience it destroys spores in a solution of one part to 20,000, and solutions of one part to 1,000, and even 5,000 are capable of destroying spores in a few minutes when applied as a spray. The same strong opinion is held by the editor of the *Druggists' Circular* who boldly asserts in the June number of the present year that no agent can compare with corrosive sublimate for the destruction of fungoid growths or bacteria so far as power and reliability are concerned, and adds that carbolic acid is far behind it as a destroyer of bacteria upon animal tissues; he has however no experience to offer of its effects upon vegetation; but admits that carbolic acid is one of our most precious antiseptics. One caution may be mentioned concerning the latter, and that is, from full and comparatively recent investigation it is

said to have no antiseptic influence when mixed with oil, It is the aqueous solution only that is reliable for the diffusion of health. Vaporizing, as now practised in the Rotunda Lying-in Hospital of Dublin and other institutions, both with carbolic acid and corrosive sublimate (one part to one thousand) is barely practical either in orchard or garden where the "broad expanse" of air covers so much unconfined space. This them could be continued to an almost indefinite extent; but what fruit growers are most concerned about is "a remedy," anti-septic rather than disinfecting; but both have been presented in this paper, and I trust will prove of some value to the future experimenter.—59, Gregory, St., Rochester, N. Y.—*Gardeners' Monthly.*

AGRICULTURE ON THE CONTINENT OF EUROPE.

(*Special Letter.*)

PARIS, 4th October.

It is alleged that cooking grain for horses aids digestion, as much grain when raw, passes through the stomach unchanged. In the case of oats, poultry find in horse-dung plenty of undigested seeds, and so much so, that the latter do not lose their germinative properties. Oats contain in their pellicle a fatty oil and an aromatic resin, which stimulate and impart a transient force, as urine does to man. Now cooking oats deprives the grain of this invigorating power. Some only steep the grain in boiling water to crack it, and so force open the feculent cellules; indigestions are thus avoided. Coachman say, too, that colds are thus kept away. In Paris, when beans are given, they are first soaked.

Agriculturists are commencing to pay more attention to the changing of seed, and the local farm societies throughout the country organize exchanges. Where wheat may be cultivated on light soils, deficient in lime, change of seed every three years is imperative. The same applies to rye, if the land be strong and humid.

Dairy farming is making important strides, and the progress is aided by the ensilage system, and the rapid consolidation of small holdings, the owners being unable to till them, and prefer to be comfortable farm laborers or immigrants to the cities than starved squatters. But the dairy mania absorbs all the milk either to be sold fresh in cities or converted into butter and skim cheese It is the situation of the fishing port that sends all its "catch" to the metropolis. The doctors complain that the rural children are becoming stunted and sickly from inability to obtain a milk diet, the substitutes of coffee—slops and beer wash—being inimical to health. It is suggested to compel farmers to pay their work-people partly in milk, or limit the export of it. One dairyman in a village solves the difficulty better; he serves the inhabitants with milk all the year round at a fixed price. Good Samaritans suggest the organisation of "Cow Clubs," for and by the needy. This might suit where there existed large landed proprietors, but in France there is only the *cottier* or the *métayer*. No proprietor would think for a moment of letting two or three acres to John Hodge to keep his cow, and so secure a supply of milk, to say nothing as to how Hodge is to obtain a shed or the capital to purchase the cow. And even had he all these aids, the chances are quite on the cards; he would enter into an arrangement to dispose of all the milk, and fall back on bogus coffee, artificial beer, or manufactured wine. In Lorrain, celebrated for its robust inhabitants, the diet during nine months of the year consists of boiled potatoes and skim milk; after each bite of taty, a spoonful of the milk is taken. And in the mountainous parts of Germany the poor hewers of wood and drawers of water have to exist on the potatoes without the milk.

M. Goffart was the apostle of the ensilage plan of conserving green forage in trenches constructed in masonry, or simply opened in a dry soil. M. A. Rouvière, of Aussillon (Tarn), is the Peter the Hermit of the plan of conservation, by stacking in the open air. He has been perfectly successful, and invites all whom it may concern to come and see. Nothing more conclusive. Thus all the expense is saved of constructing silos in masonry with cement and under special shed. There is nothing at all extraordinary in the process. The whole principle of ensilage lies in the absolute exclusion of the air by a regulated pressure from the green mass, and if such can be secured in a "stack," the preservation must be as efficacious as in a covered trench. M. Rouvière has employed the stacking in the open air of green forage since 1883. He has given the analysis of his preserved fodder, and which shows it to be as rich as that conserved in silos. This spring he saved his whole lucerne crop by stacking it green, as the spring was incessantly wet, and so prevented its drying. The following is the way to proceed:—Select the site where you please; immaterial if exposed to wind, rain, or snow; cut around an open drain to carry off the rain water, so that the bottom of the stack will be secured dry; commence the stack, which should be rectangular in form, having a width of six feet; pile the forage in even horizontal layers, and tramp down firmly at sides; place planks one inch thick and seven wide across the stack, then another row of planks to cover the joints like slates on a house; next range planks perpendicular to the first, nailing them at the ends. Let the cross planks project a little over the side. On the planks heap large stones at the rate of 16 cwt. per cubic yard, but apply only the one-half this weight the first day, and the remainder the following, when the mass shall have shrunk. The temperature will at first run up to 119 Fahr. degrees, but will speedily fall and remain stationary at 93 degrees. Leave the stack then to itself, only a slight external skin will be deteriorated. When it is desired to use the preserve, remove two or three, as may be required, of the planks and their stones, and cut the exposed mass as if a hay rick. By not placing all the stones on the stack when completed, its leaning is thus avoided. A farmer has now no excuse for not *trying* this plan with some maize, lucerne, clover, &c.

Messrs. Andouard and Dézaunay have recorded their latest experiments on the feeding of milch cows with beet pulp preserved in silos. Their conclusions on seven cows are; the pulp—from the diffusion process of sugar extraction increases the secretion of milk, and its richness in butter without affecting the quality of the latter; but it alters the flavor of the milk and accelerates its spontaneous coagulation when not corrected by green fodder; it suits fattening stock admirably. The experimenters fall into the error of concluding milch cows are fed exclusively on the pulp; they receive rations of forage, as in the case of grains, that which explains why no complaints are ever made of the milk. The butter is never the same, however, as when prepared from green or dry forage.

A useful little machine has appeared for washing bottles. It can be attached to the side of a tub, and by turning a wheel a brush is made to revolve inside the bottle, along with a continuous jet of water simultaneously pumped.

In order to revive the good old plan of women milking cows, some of the agricultural societies intend to have "milk-maid contests."

In the annual Agricultural Show to be held at Paris next February, there will be several innovations; there will be prizes for milk, for oyster culture, cider and perry, and for novelties in the *matériel* of agricultural education.

By the death of M. Barral, Secretary of the National Society of Agriculture, French agriculture loses its most brilliant representative and science one of her ablest sons.

At Rascof and elsewhere in Brittany, sea weed imparts a marvellous vegetative power to the soil. By its aid thousands of acres are cropped with artichokes, asparagus and cauliflowers for the Paris market. The weed is only allowed to be cut on a stated day, and 20,000 people at once set to work. With the aid of branches, posts, barrels, &c., immense rafts are formed to float in the cuttings which look like moving islands. Round the isles of Ouessant, the women rake the weed in from the sea; they remain for hours up to the waist in water, having their babies strapped on their shoulders to sleep or suckle as occasion needs; the waves sing a lullaby.

SURFACE CULTURE IN FRUIT FARMING.

The usual practice is to dig between the rows of soft fruit, as close to the stem as can be done conveniently. The theory on which Mr. Croose went to work was that this digging is injurious to the trees by breaking the roots, and that the proper course is to thoroughly encourage

root formation, and not only that, but to keep the roots on the surface. For three seasons, therefore, the three acres in question have not been dug, the only implement employed being the hoe. Sedulous hoeing has been carried out, in order to keep the weeds down, and because a light stirring of the surface soil has a beneficial effect. The idea is by no means to have a hermitically-sealed soil with a baked surface; but all culture is strictly superficial, to prevent root disturbance. This, of course, necessitates the application of all manures in the shape of top-dressing. None is dug in. No matter in what form it may be, whether farmyard manure, whole bone, bone dust, guano, woollen waste, skin waste, or what not, it must be left to a process of natural absorption of the soil, or to be washed in by rain, or drawn in by the sometime despised but industrious worm. The utility of this latter agent is fully recognised on Yew Tree Farm. Darwin has sufficiently demonstrated its value, and doubtless under the system of surface cultivation the action of worms is doubly useful, owing to the way in which they are continually causing minute but important displacements of the soil, and thereby preventing it from caking; while the riddling and boring which they carry on provides a means for the admission of air to the soil, which is probably invaluable. Roots, like other animate things, travel in search of food, and the constant placing of manure on the surface draws and keeps the roots near the top. Surface culture, then, combined with the superficial application of manure both tend to that undisturbed root growth, as near daylight as possible, to which Mr. Croose attaches so much importance.

An instance of the way in which the manure at the top tends to the growth of fibres, which are sent up by the main roots to the surface in search of nutriment, was pointed out to us. There is a large plum tree in the chicken run, and on kicking off a cake of the chicken dung and scratching the surface of the soil, a mass of fine heavy fibres became visible, which had been sent up by the large roots. We are aware that there is nothing particularly new in all this, but it will tend to illustrate the lines on which Mr. Croose is working.

The main reason for which Mr. Croose objects to any breaking of the roots, such as is unavoidable in digging, appears to be this. Fruit trees, from the time the sap begins to run, require all the nutriment and encouragement they can get. Thus, very soon they begin to flower, then the fruit becomes set, from which time on till the ripening there is a continual process of development. At no stage of this development—from the first budding of the flower to the completion of the ripening—can the feeders of the tree be ruptured and torn without the feeding process, on which the production of the fruit depends, being disturbed; and the supply of nutriment cannot be interfered with without the fruit suffering, at whatever stage it may be when the disturbance takes place. It will be said that the digging takes place in the winter, when the life of the tree is dormant. The answer to this is that the vitality of the tree, or some portion of it, has subsequently to be directed to repairing damages, and that while new roots are being formed the tree is suffering for the want of them. By the time these roots are formed, or partially formed, they are again ruthlessly destroyed with the digging "spud," the result being that the tree is dependent largely, if not wholly, upon the lower roots, which go into the subsoil, the richer top soil being left more or less unutilised. This subsoil makes plenty of growth, but does not produce much fruit, and although wood is necessary in any case, it is of course useless to produce it unless it will grow something marketable; an unfruitful tree will make growth simply because it is unfruitful. The energy of the plant must go somewhere—it must be expended in some form—and failing its direction to fruit, it manifests itself in an abundance of wood and leafage. Mr. Croose, however, goes in for an abundance of wood; but we shall refer to this again when we come to say a little about pruning. In the old plantation, three years without digging have resulted in the formation of a complete network or carpet of roots, those of each tree interlacing with their neighbours. On taking up a small piece of earth from between the currant bushes, it presented quite a hairy appearance, through being so full of minute fibres. This state of things would doubtless have been even more marked had the season not been so exceptionally dry.

The practical reader will look with some interest to see what Mr. Croose does in the way of manuring. He is of opinion that the growers as a rule do not pay sufficient attention to keeping up the supply of phosphates, of which there is a large amount in the ash of the fruit and wood. Everybody is alive to the need of a plentiful supply of nitrogen, which if used too freely is apt to make a lot of leaves and growth, while phosphate is more particularly required in the formation of the actual fruit. It is also needed for the production of fine flowers. People never think of making a grape border without using bones, and phosphates are just as much required for other fruit as for that of the vine. In ordinary farmyard dung, phosphates and nitrogen are both represented. It has consequently a peculiar value in this respect, and for this reason Mr. Croose uses it as far as obtainable. Fur waste, soot, shoddy and waste-product manures contain principally nitrogen, and have, therefore, only a restricted value. The much-needed phosphates are supplied on Yew Tree Farm mostly in the shape of crushed bones. Bone superphosphate which has been dissolved in vitriol is not in much favour, on the score that it makes the ground very acid. It has the merit of acting very quickly, however, and, for this reason is invaluable in certain cases. Mr. Coorse puts on about a ton of bones, crushed to quarter-inch size per acre. Owing to the slowness with which it dissolves, this is calculated to last for eight years. It is astonishing how the little fibrous roots bore into the pores, so that if you dig out one of the pieces of bone, you can hold it up by the fibres which have attached themselves to it. The presence of these slowly dissolving bones gives a permanent supply of phosphate for the formation of fruit. Nitrogen is supplied by flock dust, skin waste, soot, or Peruvian guano. All manure, as before stated, is placed on the surface, and it disappears quickly. The quarter-inch bones will vanish from sight in one ordinary season.

Allowing the cost of the bone manure (spread over eight years, and applied at the rate of a ton an acre) to cost £1 an acre yearly, the other manures used being the yearly cost for dressing alone to from £9 to £12 an acre, so that in ten years Mr. Croose would spend considerably over £1,000 in nourishing ten acres of ground. He states as a result of his system that he has been able to produce more fruit and of a finer quality; and his salesmen in Covent Garden tell him that they have been able to realize a higher price for his fruit on this latter account. Another fact is, that the fruit in his plantation has not fallen off to anything like the extent that has been the case in those around him. A somewhat unexpected result has also been attained in the case of some of the old apple trees. Three old Wellingtons stood together, cankered, lichen-covered, and apparently exhausted; one was cut down, the others were allowed to remain. Under the plentiful application of manure to the surface, a quantity of vigorous new wood has grown out, and the apples, instead of being small and cankered, are clean and fine. That this result has been attained by some means other than fresh grafting is self-evident, as the trees with the apples upon them were there to bear testimony at the time of our visit.

Mr. Croose does not believe in pruning, except to a very moderate extent. His theory is, that with his style of culture an abundance of wood should be produced. He believes that a free-growing tree—given, we presume, that it is a fairly good sort—is sure to be fruitful under his system: that is to say that, there being an abundance of root power, with plenty of fruit-forming constituents in the soil, as well as wood and leaf-producing material, the tree will, as a matter of course, succeed in carrying out its natural function of making fruit. In other words, that if all the conditions requisite to the production of fruit are supplied, in the shape of good soil, appropriate nutriment and suitable cultivation and treatment, nature may be trusted to do the rest.

In concluding our remarks we may say that, under Mr. Croose's plan of surface culture, top dressings (in which a prominent place is given to the supply of phosphates), and limited pruning, everything on the place looks remarkably thriving and healthy; nothing seems to be slouched or slurred over, and order, "heaven's first law," is clearly in the ascendant.

It occurs to us to "tag on" a general observation or two. Fruit farming has been recommended as a remedy for agricultural distress. Failing the possibility of growing a paying crop of wheat, the cereal farmer is advised to turn his attention to raising fruit. Fruit farming is not a pursuit in which success can be attained at haphazard. It requires knowledge, patience, and capital, and the man whose experience has been confined to the production of grain, grass, and roots should realise the fact that, before he can hope to replenish his depleted coffers by fruit farming, he has got to learn a new business—nothing more or less.—J. H.—*Field.*

NAPHTHALINE AS AN INSECTICIDE, ETC.

BY DR. THOMAS TAYLOR,

Microscopist of the U. S. Department of Agriculture.

About eleven years ago I had occasion to use large quantities of the dead oil of tar for commercial purposes. On removing the dead oil from the barrels I usually found a large quantity of solid matter deposited in them; it proved to be crude naphtaline which had precipitated from the "dead oil" on its cooling in the barrels.

Incidentally several bushels of the naphthaline were placed in an outshed and remained there undisturbed for a year, when I observed that its odor was in no way diminished. Being a coal-tar product, it occurred to me that it might be of service as an insecticide, and to that end I instituted a series of experiments with it on insects. I found that it had the power of producing a state of asphyxia. I also observed that different insects as well as the higher grades of animals were unequally affected. The winged phylloxera when immersed in the gas of this substance die almost instantly, while a full-grown potato bug under the same conditions would turn on its back and lie in that position for a week, manifesting life only by a slight movement of its limbs. In about ten days it dies; if not confined for too long a period, it recovers, and seems none the worse for the treatment. Their larva are quickly destroyed when the moistened powder of naphthaline is sprinkled on their bodies. The common ant will not cross over powdered naphthaline if it can avoid it. While confined in a jar containing a sprinkling of naphthaline they move about rapidly for a short period, but invariably under such conditions cast off their wings, first the right wing followed by the left in quick succession, and shortly afterwards roll on their backs and die if kept in the gas. Termites, which prove so destructive to timber in buildings, are much more easily affected by the gas than is the common ant. The common house fly seems quite spirited for a few minutes, but ultimately turns on its back, becoming asphyxiated; but a fly may be experimented with a great many times without apparent injury by exposing it to fresh air and odor of naphthaline alternately, while if confined in the odor for too long a period it will die. The common large blue fly (Musca Calephora) if a female and pregnant invariably aborts when asphyxiated with the odors. This fact may be of some importance physiologically. After aborting the fly seems as lively as if it had not been subjected to the influence of the gas, and as if no change in its condition had occurred. Honey bees and wasps are affected in the same manner as house flies. Honey bees in the hive may be anæsthetized by placing about an ounce of the pure white powder of naphthaline on the floor of the hive, and carefully watching the effects of the naphthaline on them when the bees are asleep; the hive may be uncovered and moths and honey removed.

If a small portion of naphthaline is placed in the holes of rats and mice they quickly vacate them and will not return until the odor of the gas has disappeared. Frogs, young and old, become asphyxiated in this gas, and die only when kept long under its influence, although I have seen a young frog remain torpid under its influence for a period of twelve hours, afterwards recovering from the stupor apparently in a healthy condition.

Several of the European governments have prohibited by enactment the importation into their dominions of plants, cuttings, bulbs, etc., from any country or district where the phylloxera of the grape-vine is found, with the view of preventing any further introduction of that insect into their vine-growing districts. I made the suggestion several years ago that a few grains of naphthaline be placed in small packages containing cuttings, bulbs intended for exportation; its odors would destroy nearly every description of insect present without injury to the plants.

Great loss is sustained by farmers through the introduction of a variety of insects into the United States from abroad through the medium of grain. In many cases this might be easily prevented by simply placing a small bag containing an ounce or so of naphthaline powder within the packages, as already mentioned, before shipment. By confining the naphthaline in bags the odor will permeate the entire sack of grain, and when desired the naphthaline bag with its contents could be easily removed. This might be useful, especially when the grain is intended for seed purposes. About six years ago a sack of superior sorghum seed had been bought for distribution by the Agricultural Department. While it was in the seed-room, one of the employees heard sounds proceeding from the sack; on my attention being called to it, I examined the seed and found it alive with minute beetles, which accounted for the sound. I placed a pint of these seeds into a quart bottle, and combined with them a small portion of pure naphthaline. Within an hour the sound ceased, and upon inspection the insects were found to be destroyed. These seeds were retained in the jar for a period of two years, and were planted (by Mr. Wm. Saunders, in charge of the propagating garden of the Agricultural Department) to test them. They germinated and grew, thus showing that the germ of the seed was uninjured. The odor of the naphthaline in the bottle which contained the sorghum seed was as strong as when first applied to it.

Although naphthaline has many practical uses, it has its disadvantages. The direct rays of the sun falling on it in exposed places caused it to evaporate, and thus quickly destroy its usefulness.

In applying it on open ground, insects, such as crickets grasshoppers, and roaches, will simply avoid it, but when put in the ground near the roots of plants or trees it will have a beneficial effect, as the odors will drive away all insects, or destroy them should they remain.

When combined with water it acts more quickly on the larva of insects than in the dry state. Worms, caterpillars, and even roaches and the larva of the potato bug, evince pain when the solution comes in contact with the tender parts of their bodies.

Large beetles resist its effects for several days. I have observed a black species of roach survive, while the common brown species died under the same treatment. One of the gardeners of the Department of Agriculture discovered one evening that a beetle was at work gnawing the leaves of one of his rose bushes. On looking around he found that many of his bushes had been destroyed. This led him to dig up the ground around the bushesi with the hope that the beetles would be found, and to his gratification and surprise he found about fifty full-grown beetles, measuring about an inch in length and nearly one-half inch in diameter. I procured several of these beetles alive, and subjected them to the ordors of naphthaline for a reasonable time without producing stupor. Finding it was not likely that naphthaline could be successfully used as an agent for their destruction, it occurred to me that a still stronger chemical might give more satisfactory results. For this purpose I used labarax solution (chlorinated soda.) In this solution chlorine exists in the free state, which is very offensive to insects.

I put a small portion of the labarax solution in an ounce vial, and placed it under a receiver, together with three full-grown rose beetles. The free chlorine issuing from the solution quickly filled the receiver, when the beetles began to move about rapidly. Within a few minutes it was evident that they were very much affected by the chlorine. In a short time they rolled over on their backs and died. For some purposes, therefore, the labarax solution might be employed with better effect than naphthaline. But it should be observed that delicate roots are quickly destroyed by chlorine.

Several years ago I made a number of experiments on plants growing in the hot-house of the Department in the presence of Mr. Wm. Saunders. Observing a large banana plant infested with ants, I sprinkled pure naphthaline on the ground around the plant. The ants, which were descending in thousands to the ground, retraced their march on discovering the naphthaline odor. Higher up on the banana

plant they found the leaves and branches of a neighboring plant touching the banana, by which they were enabled to descend to the ground.

Insects on growing plants have been placed in a closet and under glass covers, and subjected to the odors of the gas; the insects were destroyed, particularly aphides.

On one occasion I removed a geranium with the earth attached from its pot, and cut about an inch of the earth and roots from it. A corresponding amount of pure naphthaline was put into the earthen pot and the plant replaced. A quantity of naphthaline was also placed on the surface of the pot, and watered in the usual way for a period of several days, but no evil effects were observed on the plant. In this experiment two earth-worms were found dead outside the pot, the odors having driven them from their abode.

About twelve months ago a quantity of peas was received at the Department of Agriculture. They were found to be half eaten and swarming with small beetles. I placed a pint of these peas in a jar with a small portion of naphthaline, which quickly destroyed the insects.

A few days ago I had planted in the hot-house of the Department of Agriculture a portion of this same lot. They are in healthy growth, showing that the germs were not many way injured, although confined for twelve months in this gas.

On last Saturday I placed these three tender plants in an atmosphere of naphthaline, and kept them in that state for a period of thirty-six hours, being thirty-five hours longer than was necessary for the destruction of minute insects. I observe that a single leaf on two of these plants has wilted. The third is wholly unaffected.

Since the above experiments were made I have subjected a young carp about four inches in length to the action of naphthaline, by placing an ounce of the drug in about two gallons of water, in which the fish was swimming. For a period of ten hours the fish was seemingly unaffected. On the following morning it was found floating on the surface dead. The cornea of both its eyes had become of whitish translucent color; otherwise no peculiarity was observed.

[Read at the fifty-fourth regular meeting of the Biological Society of Washington, December 28th, 1883, held in the U. S. National Museum.]—*Gardeners' Monthly.*

COCONUT-PLANTING:

AS PRACTISED IN THE LOWCOUNTRY OF CEYLON.

To resume,* the calculation of proceeds of a coconut plantation according to the Goiya system was last touched upon. The next paragraph gives "another sketch of a plantation that was cleared and planted and allowed to grow into jungle for 12 months. At the end of that period the jungle was "10 feet high," with all the plants, less four, destroyed by wild pigs. One can but conjecture the damage done, as the acreage of the plantation is not given. The proprietor of this plantation, we are told, had much pluck and went to work the next year on a new system. He rooted out all the jungle at an expense of R20 the acre, and planted the land with manioc. The wild pigs fancied the manioc more than the coconut plants, and about 70 per cent were saved. The vacancies were supplied twice a year, yet at the end of nine years they amounted to 10 per cent. During all these years the place was kept in order, and the pasturage was rich. At the end of the fourth year cattle were put on the plantation, but securely tethered against damaging the coconut plants. Before the place was five years old, 10 per cent of the plants had commenced to bear, and seventy-five per cent of the plants treated with cattle manure were in bearing before the ninth year; its further progress cannot be stated. as the place has not gone beyond the ninth year. The trees, we are told, that had commenced to bear three years ago will, allowing for all contingencies, yield on an average 80 nuts per tree, or 5,600 the acre, which at R30 the thousand, will give the handsome return of R180. The lucky proprietor of this model plantation, we are told, will not wish it to be known that he has spent over R200 the acre on the place, without the further fact receiving publicity, that by the end of the twelth year he expects the yield to cover every penny of principal and interest, and give him a very valuable property besides. To which I may be allowed to add, that the proprietor must be a very sanguine man indeed, to calculate yield three years hence with such confidence and nicety. Instinct points to the writer of the essay, who never allows the small qualifying word "about" to disturb his calculations, and to this sanguine proprietor, as one and the same person. The only manure applied to the property was one-third of a ton of quick lime at a cost of R7·50. The high expenditure was owing to every work being experimental and the soil being rich, which of necessity made weeding, &c., heavy. A portion of this property, which received similar treatment to the rest, but did not receive any cattle manure, is so backward in growth as not to show even stem as yet. This, to me, does not speak much for the soil. Fancy trees nine years old not shewing stem as yet! But they are to receive yearly doses of poonac till they come up to the forward plants.

We are next told how an old plantation 21 years old and with a poor sandy soil was treated, and how it responded to the treatment. The largest crop it had given was at the period named, and it averaged 13½ nuts per tree. A new manager assumed charge at this period, and submitted a scheme which added 10 per cent to the annual expenditure. It was at first opposed, but finally allowed. As a first step all the pigs were disposed of, as also one-third of the cattle. The rest were allowed free access to the poonac tubs, and had a roomy shed allowed them, which was daily littered with jungle stuff and ferns from the low grounds on the estate. When the rains commenced, all the manure that had accumulated was carted and spread on the surface of the ground at the rate of 2½ cubic feet to each tree, and dug in with mamoties. Not much could be done in this way, as it would have taken 12 years to go the round of the estate, while the effects of the manure last only three years; but, as a result, the average yield per tree went up to 21 nuts in six years. Steamed bones were next used, of which two tons were allowed annually, with the result of the yield running up to 33½ nuts per tree in the eleventh year. The estate next fell into the hands of natives, who allowed the yield to fall to 12 nuts per tree. The whole cost of manuring during the 18 years was R1 per tree, and the result over R3, giving a return of 300 per cent on the outlay. We are authoritatively told that if five times the amount had been expended, the results would have been proportionate.

The next paragraph is a small lecture on Chemistry, and tells us that the writer looks upon the coconut tree "as a chemical apparatus for turning carbon, oxygen and hydrogen into oil." Plants draw the whole supply of these elements from the air, therefore no quantity of oil removed from a given area of land impoverishes the soil. But to make oil, the coconut tree must needs grow, and to grow it draws from the soil nitrates, phosphates and alkalies. If oil only is removed from a land, and all the other products of the coconut tree returned to it, the average yield of oil will never decrease as long as the tree is in health. Introduce outside supplies of nitrates, phosphates and alkalies, and the yield of oil will increase and the soil be improved. I trust your readers appreciate this little, simple lecture.

We are next told to "replace fertility removed," which is very good and sensible advice, but the process of calculation is not so easy as one could wish. "Ascertain the average of the fertilizing elements removed in a given number of nuts and set aside such proportion of the price as will replace them." Rather a difficult calculation I should say. The surest way is to manufacture oil and to retain the poonac, but if the crops be sold as gathered, the planter must know exactly how much "nitrate, phosphate and alkalies are in a candy of copperah, and their prices," so as to purchase such fertilizers for application to his land. Beautiful in theory, but difficult of practice. One hundred and fifty pounds of poonac, we are informed, will replace the fertility removed by 1,000 nuts, so that that is the cheapest and best manure for coconuts, especially if passed through a cow.

The manure resulting from cattle only grazed on a land does dot add to its fertility, but it is of great importance that such manure should be placed at the roots of young coconut plants which do not go far in search for food, as aids to rapid growth and early bearing. The benefit the plants will derive will not be only from the food thus placed within their reach, but the roots will be stimulated to increase their feeding ground. It is more bene-

* See *T. A.*, p. 375.

ficial to give small and frequent doses of manure to a tree than large doses at long intervals. The manure must be buried below the surface. When planting, put in each hole a couple handsful of lime and a pound of poonac. A tree cannot be expected to yield two or three rupees annually, unless its constitution is built up. The writer of the essay, whose dicta the above are, will spend 50 cents per tree during the first seven years "in building it up," after which, within four years, it will give a return of three nuts for every five cents of manure used. Mark the confidence and certainty with which results are given. The manure and its price too are known quantities in the calculation. There is no practical limit to the yield of a tree; the writer of the essay is acquainted with trees bearing from 200 to 400 nuts each annually for a series of years, but that is owing to the "individuality of the tree" and suitable soil. The contention of the essayist, which nobody ever did or will question, is that any tree bearing a small crop in any soil, can be made to increase its yield. "A good soil gives a good crop without assistance, while a poor one gives a poor return, but the one will respond to manure as readily as the other." Here the essayist delivers himself like a practical planter, and not as usual as a theorist; but he has forgotten one little question, which every practical planter who has a regard for his own or his employer's purse will put, before he undertakes to increase the yield of "any" tree on "any" soil—"Will the increased yield cover the cost of inducing it?" That is a safe test to apply to all such undertakings. I am afraid no practical planter will accept the next statement that "the same amount of manure will result in the same addition to the crop, whether the trees to which it is administered have previously been bearing ten or fifty nuts per annum."

The next paragraph deals with "the treatment of a single tree and results," and opens with the startling statement that a stem of a coconut tree on poor land forms a complete register of the periods at which manure had been applied, the effects it produced, and the time during which it operated and became exhausted. How the appearance of the stem of a coconut tree could indicate what crops it bore when manured, for the *effect* of manure is always gauged by the resulting crops, and the period of time the crops were affected by the manure, passes my poor comprehension. [The effect on the stem is obviously meant.—ED. "EX."] It is well known that on poor soils, neglected coconut trees gradually taper towards the top. A little attention, not necessarily manuring, causes the stem to bulge out again, so that a practised eye could easily detect if a property had been neglected for any length of time and taken in hand again. But for any one to say he can give the effects of such renewed attention, or name the period of time the improvement consequent on such attention lasted, is rubbish.

Now for the account of the tree that yielded astonishing results by the application of manure. The tree existed for twenty-five years on such poor and sandy soil, as no other form of vegetation would grow on. The stem was one foot in diameter at the base and tapered to four inches at the five feet to which it had attained. The leaves measured about thirty inches. No worse specimen of a living plant could be selected, but it was operated upon for the sake of experiment. Twenty pounds of poonac and five pounds of steamed bones were mixed and dug in round the tree in a circle twelve feet in diameter. The growth was vigorous, and within a twelve month the new leaves had attained a length of fifteen feet. At eighteen months the first flower showed itself, and the tree again received five pounds of poonac and two of bones. At thirty months it began to give a crop so heavy that fears were entertained of the steam snapping at the thin portion. The same dose of manure was given for the three succeeding years. At the end of the fifth year the wretched specimen had developed into a handsome tree, with the stem at the top over one foot in diameter, and carrying a crop of 60 to 70 nuts, while the previous crops aggregated over 100 nuts. According to the writer, this handsome tree was built up and yielded 170 nuts, with an expenditure of only 75 cents for the 40 lb. of poonac and 13 lb. of bones applied over a period of five years. A very handsome return indeed, and a fit reward for five years of patient attention to a tree described as "the most wretched specimen of a still living plant." How many owning trees answering to this description will feel cheered by this experiment, and be inspired with hope! After this no one will deny the essayist the right to raise himself on a pedestal of his own making, to assert his own superiority over his brother planters, and with a feeling of pity for their ignorance to address them thus:—"There are truths that science has made common property, but which few coconut planters have yet asserted their right in, or indeed become aware of their existence. How few of them know that 187 lb. of poonac contains (*sic*) all the elements that is (*sic*) removed from the soil in a candy of copperah? How few of them know that the poorest soil may contain some of the elements of fertility that the plant cannot assimilate from the absence or deficiency of other necessary elements? A few measures of quicklime may bring into activity a great fund of latent fertility: a few ounces of bone dust may be the one thing wanting to put a good crop on a barren tree." A sigh of pity is next heard for the poor ignorant goiya, who, we are told, would pronounce the principles of Agricultural Chemistry, if propounded to him, a myth, and the propounder a humbug. No general knowledge of Agricultural Chemistry is possible till the Agricultural School turns its graduates "loose on Society." Next comes a fling at Europeans, of whom "not half a score know anything of coconuts." Then an all-round thrust at proprietors, who, though educated and intelligent, "will not deign to look on the scientific aspect of the culture."

I am not one of those who hold it as "an incontrovertible rule" that coconut plants not in bearing should not be manured. What I hold and practise is that laggards should be stimulated and fed to keep pace with the other plants in a field. But I am most decidedly of opinion that plants shewing satisfactory and fair growth should not be stimulated into early bearing, *if* you wish your plantation to be a permanency. Experience and observation alike teach us that precocity and longevity are not synonymous, but opposite, terms.—Ceylon "Examiner."

DR. SCHULTZ has added another article to our already long list of antiseptics. This time it is one that cannot be objected to on the grounds of being poisonous. Citric acid is the new preventive of putrefaction. A 5 per cent solution is claimed to preserve meat. The value of citric acid for this purpose can be easily tested by any one.—*Independent Journal.*

SOILS.—All attempts to improve the nature of a soil should have for their object the bringing it to a state of loam, by the addition of those substances which are deficient. If there is too much clay, chalk and sand may be added, or a portion of the clay may be calcined by burning, in order to destroy its attraction for water, and thus act the part of sand in forming the loam. Limestone, or calcareous sand and gravel, are still more efficacious for this purpose; they not only correct too great porosity, or too great tenacity, but also act chemically on the organic matter in the soil, rendering the humus soluble, and fit to be taken up by the roots of plants. If there is too much sand, marl composed of clay and chalk is the remedy. Good loams require much less tillage than stiffer soils, and will bear more stirring to clean them than sands. Hence they are cultivated more economically, and more easily kept free from useless weeds; while the produce is more certain and abundant. They can be impregnated to a higher degree with enriching manures, without danger of root-fallen crops, or of too great an abundance of straw at the expense of the grain. If there should be means of irrigation, no soil is better suited to it than a light loam on a bed of gravel; or even if the subsoil is clay, provided sufficient under draining prevent the water from stagnating between the soil and subsoil, which, as practical men very properly express it, would poison any land. A loamy soil requires less dung to keep it in heart than either clay or sand; for while it is favourable to the process by which organic matter buried deep in the soil is converted into insoluble humus, it also permits that part of it which is nearer to the surface to attract oxygen from the air, and thus it is converted into a soluble extract, which is to the roots of plants what the milk of animals is to their young—a ready prepared food, easily converted into vegetable juices.—*The Gardeners' and Farmers' Reason Why.*

A BOTANICAL VISITOR ON VEGETATION AND AGRICULTURE IN SOUTHERN INDIA.

Madras.—Availing myself of two months' leave in November and December, 1883, I visited South India, which I had not seen before. Madras I found hot and uninteresting, but I was repaid by a sight of the Crotons in the compound of the Holy Emanuel Church. They are a marvel of beauty, and of all forms, sizes, and colours of leaf. The compound glowed with colour. Some fine specimens were upwards of 6 feet high. The best I thought was the C. pictus. I never suspected what a charming beauty this was till I saw it here. These Crotons alone were worth coming to Madras to see. There were still finer specimens of some kinds in the horticultural garden. Crotons are great favourites in Madras, and justly so. A fine bush of them is a great feast for the eye. They are much used for decorating verandahs and porticos, and they appear to like the sea air.

All the trees I saw in this capital appeared as of yesterday. In vain did I search for some fine old trees either on the roadsides, or in compounds, or anywhere; while, on the other hand, the whole place looked so ancient. I saw no fine avenues. In such a climate there should have been no difficulty in growing trees with fine foliage; they would add grandeur to the future Madras to which the people are aspiring. Many of the trees on the roads are ugly specimens of the Thespesia populnea, which would have been better suited to Dante's *Inferno*, as illustrated by Doré.

In the People's Park, the only interesting things I saw were two cubs. They assured me that these were hybrids between a wolf and a "pariah" dog. The parents I saw also. The father was an ordinary Indian wolf, and the mother, a black pariah, with a white neck and white feet. The cubs were wolf-like, of a fawn colour, and one of them had a white foot. I tried to ascertain whether such a fact had been recorded, but could not find that anybody took any interest in such matters.

The Masula boatmen interested me much. I thought them among the finest specimens of men I had seen anywhere. Although not so heavy as navvies, their muscular development is superb. The muscles of their legs, thighs, trunk, arms, shoulders and neck, are all equally well developed. One does not see such fine specimens, except among acrobats. They are middle-sized men, and are pictures of health and strength. There is a curious and erroneous notion, which unfortunately has found its way into scientific books, that people in the tropics live upon Rice and vegetables. No greater delusion. These Masula boatmen eat plenty of mutton or beef, according to religion, plenty of fish, rice and vegetables, and drink a good deal of toddy, or "arrack," brought from Colombo. Their only covering is a small loin-cloth; they are exposed to the rain and the sea, and work hard. Whatever cargoes come to and go from Madras are landed and shipped by them. Among them are Mohamedans, Hindoos, and Roman Catholics, and they all appear to pull well together in one boat. I left Madras with the feeling that I should not like to have been the designer of its fountains!

Bangalore.—I looked in at Bangalore, as I had often heard that this is the station of South India. It is a fine place certainly, with a fine climate. I was told punkahs are not generally used there, excepting on hot days at meals. There are many regiments stationed at Bangalore. The Cubbon Park is an extensive place, with a fine large building over-looking from an upper terrace. The building is of a brick-red colour, and in it are the Government offices. In the Park I saw a number of Mango trees (the grafted Mango grows well), and many of Pongamia glabra. I saw a few Araucarias, and many ugly-shaped Casuarinas; in fact, I hardly think I saw one well-shaped Casuarina. These were queer trees. Some grow as straight as an arrow, others fork, and many grow crooked and all ways. While yet in the nursery it is not difficult to recognise which are likely to grow straight. Those that do, often make fine trees, and the others are not worth having. The Poinsettias were in flower, and very fine, equal to those of the Mediterranean. I saw a few trees here which are worthy of notice. They are the Schinus molle, or Pepper tree. In the Mediterranean this tree grows well, but cannot be grown even so far north as Rome, on account of the frost. I tried it largely in Lucknow. The damp, hot weather of the rainy season killed it. In the Cubbon Park there were four trees as large as those on the Mediterranean, but, perhaps for want of a rich soil, not so fully clothed with foliage. It is a very graceful tree, and why they do not grow more of it in Bangalore I do not know. Its growing well there indicates, I think, that the climate during the winter is like that of the Mediterranean, and that in summer it is free from the hothouse dampness of the tropics. I saw a group of the Spathodea campanulata (this is the name on the ticket). This is a tall tree, with unusually dark green foliage, interspersed with masses of scarlet bell-shaped flowers, turned upwards. At a short distance they look like bunches of scarlet Pelargoniums. The tree is a perfect marvel of the vegetable world, and matched only, I think, by the Poinciana regia. Its common name is "flame of the forest." An avenue of Spathodeas, full grown, and in full bloom, would be a subject on which to write a poem: The charm of this tree is that it flowers in winter. Will no one try to immortalise himself by planting such an avenue in Bangalore? It is a curious thing that close to the red brick building masses of Poinsettias have been planted. Masses of Cupressus sempervirens, which in Bangalore grows superbly, would have been far more appropriate. The soil appears generally good; no artificial irrigation is used, excepting when the trees are growing, and the grass is everywhere fine in this park. The fallen leaves are carefully swept away. This is well, if they are rotted, and afterwards returned to the roots of the trees. This is not done, and most of the trees bear evidence of a want of leaf-mould. When will people learn that the best manure for a tree is its own decayed leaves?

On the way to the Lal Bagh at Bangalore there are various native nurserymen. I went into B. Nagappah & Co.'s nursery and was much pleased to find there an extensive collection of well grown decorative plants, and all very moderate in price. This firm appears to carry on a thriving business, not only in Bangalore, but also with various parts of South and Central India and Ceylon. They publish a catalogue of plants and seeds; somebody should, however, help them to put down the right botanical names. For Schinus Molle, they have Chinese mulli. They have also a Splendunus variegata, which probably would prove new to botanists! Most of the names are well hit off.

The Lal Bagh is a charming garden, with terraces and parterres. Here a pretty use is made of the Bignonia gracilis. It covers a sloping trellis, which forms the verandah of a pic-nic shed. Its elegant slender branches hang very prettily from the eaves—the perfection of gracefulness. Near the band-stand are two perfect specimens of Spathodea. The white and purple Meyenia are splendid here, and very floriferous. These, however, and the Hamelia patens are tortured into shapes of huge balloons and buttons. I remember seeing at some station on the East Indian Railway the tops of a "Mehndi" hedge (Lawsonia inermis) clipped into figures of elephants, temples, dogs and donkeys. This is excusable in a native gardener, but to carry on such a system in the Lal Bagh, Bangalore, where huge iron embossed botanical tickets are used, is not only out of place, but, I think, unpardonable. There are some fine specimens of Cupressus sempervirens as straight as an arrow, and between 40 and 50 feet high, and beautifully clothed with foliage from top to bottom. There are, however, too few of them, and they are stuck about singly, like solitary unmeaning pillars. Some thousands of them, grouped in striking masses, would be very effective.

The Tamarind tree grows well, but is nowhere used for avenues. Those who have been to Fyzabad, in Oudh, know what a famous tree the Tamarind is. Curiously enough, in Bangalore, I saw only one plant of the Bougainvillea glabra. They have the spectabilis, which flowers only once a year; nowhere have I seen anything like the "fireworks" of Bouganvillea glabra which there are in Lucknow. The Grevillea robusta makes a pretty road tree. The Lal Bagh is a great place for promenades on band evenings. One evening the European cavalry band was playing under a pretty kiosk-like place. The Bangalore society were promenading about the terraces and parterres. I was snugly seated on a high bit of ground under a Spathodea. For a few moments I allowed myself to dream that I was in Versailles! Here they use the beautiful large single red Hibiscus rosa sinensis for hedges, and they clip them! I saw a fine untouched bush of this same Hibiscus in the

shade of a pretty tree, with its base fringed with Fern and painted leaves; it was unique, and worth more than a mile of the clipped hedge. I saw a European Olive tree, and also a Carob tree; both looked healthy. I should not wonder if Mysore, with its almost Mediterranean climate, were suited to these trees. The Cocoa-nut Palm grows well, and so do other Palms, but nowhere are they used for decorative purposes. I have not seen one specimen of Lombardy Poplar, although it ought to do well in such a climate. They have two Figs, the Ficus comosa and Benjamina, which are very pretty and suited for avenues. All over Bangalore there is an infinity of trees of the Poinciana regia. What a conflagration in the spring! Then, one would almost require tinted spectacles to save his eyes from the blaze—I did not see, however, a single decent avenue of any sort; such as would make you stop and look at it again and again, and say within yourself, "How fine!" All are of the "higgledy-piggledy" style. In one line are planted a number of incongruous trees that cannot by their nature ever form a line. All avenues, in fact, are planted like this in India. In all my travels from north to south I have not yet seen one avenue worth looking at, except the Tamarind one at Fyzabad, and that, I was told, was planted by a Rani "somebody" long before the British occupation. I liked Bangalore very much, but I left it with the impression that they may have engineers and gardeners there, but there was no trace of artists. With such wealth of trees and shrubs growing in the open air, what a paradise a landscape gardener might make of this military capital of South India, with its fine Mediterranean climate!

THE NILGIRIS.—From Bangalore I took the train to Metapollum, at the foot of the Nilgiri Mountains. Between this station and the Kallar River there is a forest of the Betel-nut Palm, which is very fine. Conoor is the first hill station one comes to. It is an exceedingly pretty place, with Tea, Coffee, Cinchona, and Eucalyptus plantations in all directions. Some of the Eucalypti I thought 100 feet high. When young the E. globulus makes the hillside look quite blue. Camellias thrive in the open air, but they have a horrid way of chopping off their heads. I think this both a stupid and a barbarous way of pruning a lovely bush. In Florence I have seen Camellia bushes 20 feet high. As to Heliotrope, this appears to be the home for it. Opposite my hotel window there was a bank of Heliotrope 80 paces long and 3 feet broad, covered with exquisitely scented flowers. It grows like a weed at Conoor. Tree Ferns grow well, I saw some 10 feet high. Here I saw a fine specimen of the Agave americana variegata. It was 6 or 7 feet high, and a perfect picture; also a Brugmansia suaveolens, 12 feet high, covered with its enchanting white trumpet-flowers. Conoor ought to be a fine place for Oleander; I did not, however, see one. Sim's Park is a pretty place enough, but the whole of it is dotted with trees of all sorts without the ghost of a notion of grouping for effect. All this is very exasperating to an artistic eye.

Ootacamund is certainly colder and drier in winter than Conoor. It is much more elevated, but on the whole, Conoor is a prettier place. Ooty, as they call it, is much more extensive, and commands far finer views Both at Conoor and Ooty the roads are passable for pony carriages, and also for larger vehicles at Ooty; there are forests of Eucalyptus globulus everywhere. It is quite changing the aspect of the hills; the Acacia melanoxylon is also plentiful; the latter is a grand tree; Grevillea robusta also grows well. Another Australian tree is the Acacia decurrens. It sends its roots in all directions, throwing up root-shoots all along. They are beginning to fear that, if it has time enough, it will overrun the whole place, and will be to the Nilgiri hills what the rabbit has become to Australia. The owners of property about Ooty appear to have been bitten by an Acacio-Eucalyptic mania. They think of planting nothing but "Ashtilon" and "Blogoom," as the natives have christened them. At Ooty they make hedges of the scarlet Pelargonium, a little pink Rose, and the little Fuchsia that grows so well in the South of Ireland and the Channel Islands, but they are all "higgledy-piggledy." A double scarlet Pelargonium trained against the wall of a house looked well. The gem of Ooty, however, is the Richardia æthiopica. In many of the watercourses are to be seen small forests of it with magnificent tall foliage, and masses of white flowers 10 inches from base to tip, and proportionally broad. It is worth coming to the Nilgiri to see this fine thing. A visit to the Botanic Garden was rather disappointing; it contains many interesting trees. I saw here some good specimens of Datura sanguinea, and a hedge of Heliotrope more than 130 paces long, and about 3 or 4 feet broad. Hitherto I fancy Cinchona planting had absorbed most attention. They have hothouse nurseries for Cinchonas, and at the time I visited the place they were filled with seedlings. The wild crimson Rhododendron, with its charming foliage, is very lovely, yet it is never used for decorative purposes. In the Nilgiri they prick out young Eucalypti into cylindrical pots made of Bamboo basketwork, and when established they are planted out, basket and all. This dodge I fancy might be used for other trees and climates. The roots are not disturbed, and the pot soon rots. The life of a planter in the Nilgiri ought to be a charming occupation. Tea, Coffee, and Cinchona, all do well in one place or another. At present quantity appears to be the object, but I fancy a time will come when smaller estates, with higher cultivation and better produce, will probably pay as well as large estates do now. I think the future of these products is great, not perhaps in value, but in extent of use. The people of India have not been tapped yet, as far as Tea and Coffee are concerned. Africa has not been touched as far as regards Tea. The manufacture of theine and caffeine may yet possibly absorb millions of pounds of Tea and Coffee. Wherever there is a change of temperature and consequent chill, fevers, neuralgias, &c., will occur—that is, everywhere—and quinine will be used if cheap enough. I fancy many young fellows come out as planters who have not a ghost of a notion what plants mean. They hear there is lots of sport—"shikar"—and out they come provided with a battery of sporting guns, and hope to make a fortune in five or six years! Thus I fancy a good deal of loss of time and labour occurs from simple want of the proper knowledge. One afternoon, on my return to Conoor, I was strolling about, and saw an opening to a hill; I went up to see what it was like. The hill had Tea, Cinchona, and Eucalyptus, all mixed up. From the age of the different plants I came to the conclusion that the owner had first planted Tea—very few then remained. Then he must have tried Cinchona, and that did not do. Finally he must have said, "Hang it! I must get something out of this property," and planted it with "Blogoom." It appeared a dry waterless hill, without a trace of leaf mould anywhere. This was a specimen of what an untrained planter would do—everything at random, as if he were at a gambling table.

TRICHINOPOLI.—After leaving the Nilghiri I went to Trichinopoli and Madura to see the famous temples there. In those latitudes they use the Agati grandiflora, the "Agast" of the North-west Provinces (a small tree with large and quaint Pea-shaped flowers), for two purposes—Its, the leaves and tender shoots and flowers are extensively used by natives as vegetables; 2nd, when the tree grows it is used for shading the "Pân" Vine and Turmeric, or such-like crops. They sow its seed thickly on ridges about a foot or so broad, and use it while young for vegetables, leaving here and there one plant to grow into a small tree. The heads of these trees then meet, and as the leaves are long and pinnate they form a very effective "chickhouse" shade. Without some such shading the direct sun's rays would scorch the tender plants beneath. The trees down South are principally Cocoa and Fan Palms. I fancy the latter is a Borassus and used for making "toddy." Of all pretty things a grove of Cocoa-nut Palms is certainly not one of the least. When about one-third grown, and under that, it is one of the most charming of Palms, and yet curiously enough, only between Pasur and Unjaloor, and further on near the South Indian Railway, have I seen any attempt to plant an avenue of Cocoa-nut Palms put in singly. Rows, three deep, would make a marvellous avenue, so would the Borassus, Phœnix, and other Palms. It is strange that down south I have seen no crops of Pine-apple. With the climate and moisture of South India it would appear the Pine-apple would grow like a weed one of the favourite crops is the Plantain. What gardens might be made in South India with little or no trouble!

THE DECCAN.—The public garden at Hyderabad is unique; all its roads are lined on each side with three rows of ugly crooked pots, with hardly anything in them. The road thither is like a desert, but here and there, where wells have

been dug, it is astonishing how fertile the soil is, and how luxuriant the trees on it are. In nooks and corners I have seen splendid oases, containing Cocoa and Areca-nut, and Borassus Palms, Plantains, Tamarind, and Custard Apples (the latter, by-the-bye, grows wild in the Deccan), Agaves, Poincianas, Hibiscus, &c. This would appear the region to introduce from Arabia the scores of fine kinds of Date Palm, of which Palgrave speaks so highly; and this would appear also the place to introduce the fine kinds of Prickly Pear, which does so well in Malta and Sicily on rocky soil; the Vine and the Olive might probably do well also. The soil, which is formed of the detritus of granite rocks, with ordinary manure and water, is immensely fertile. All along the railway from about Raichore to Dhond and Maumar, for hundreds of miles, and as the eye can see on both sides of the railway, there is scarcely any cultivation, only here and there in patches. Scarcely a village is to be seen, and not a tree, beyond now and again one, a few feet high. In all that tract of country I did not notice more than a dozen head of cattle. There are immense tracts of territory, in the state of prairie, with grass growing over the surface everywhere. There is no such thing as "oosur" (barren) land, as in the North-west province. Here and there rock crops up above the surfaces, but mostly it is a grass covered plain. They say the rock, being near the surface, and the rains being uncertain, the land is not brought into cultivation. This may be partially true, nevertheless, near the railway stations Mango and "Neem" trees, with irrigation, do very well; and at one particular station, Chitali, I saw Oranges, Guava, Pomegranates, and Mulberry growing most vigorously. I have a notion that this country might be terraced, and faith! there are stones enough to terrace the whole country. Then either by wells or tanks, or canals, I believe this land might be reclaimed. The climate is fair, in winter charming, and the Carob, Olive, Fig, Pomegranate, Mulberry, Vine, Orange, Prickly Pear, all delighting in rocky soils, would probably do well. I believe the real difficulty is about water. From what I saw of the country round Hyderabad and Secunderabad I am inclined to think that the soil, although slight, would do much if water could be collected in reservoirs or brought by canals. I do not believe in the rock theory. Just consider what they do in Malta, Gozo, and Sicily, with the rock near the surface. The markets there are always stocked with vegetables and fruit, but then they collect and store every drop of water they can. In other parts of India, where it is important that water should be stored, you see a great want of sense. On the hills, for instance, the rain-water is allowed to run away, and then mules are sent to the bottom of the "Khuds" to bring water from springs—not only for drinking purposes, but for all purposes! In most towns of Italy all the water from the roofs of the houses is collected and stored.

All about the country I have been just describing, and further south, there grows a wild Prickly Pear: I think it is called Opuntia Dilleni. It bears a small red fruit, which is tasteless, but which poor people eat. It is almost certain that the Mediterranean Prickly Pear—Cactus Opuntia they used to call it—can be readily grafted on the Deccan and South Indian indigenous kind. In Sicily at certain seasons the people live on the fruit of the Prickly Pear, which, though it contains many seeds, is delicious.

Before returning to Etawah, on reaching Allahabad, I took a run to Calcutta to see the Exhibition. I went to the Royal Botanic Garden at Seebpore, and was much delighted to see there an avenue of Borassus flabelliformis, which is magnificent, and quite unique; another of Saraca and Mahogany, one of Terminalia Catappa, and one of In Saman, alternating with Uvaria longifolia. There are also avenues of Oreodoxa regia, with its clean, pillar-like stem. I thought that an avenue of Elæocarpus longifolia would be a glory. I saw here fine specimens of the Areca madagascariensis, with its Bamboo-like stems and feathery heads, and many other fine things too numerous to mention. All this shows what can be done in that climate with proper selection of trees. You go all over Calcutta and will hardly see a tree worth looking at, except perhaps at that little oasis called the Eden Gardens.

There is one thing I saw during my travels which I must not forget to mention in conclusion. At the hotels of Bangalore, Conoor, and Ooty, the table-servant, or "boy," as they call him in South India, used to decorate the dining-table cloth every day with various coloured leaves and flowers disposed in patterns. The leaves used were those of Coleus, Croton, &c., and the flowers were Fuchsias Cupheas, and various others. Sometimes the table looked charming.—E. BONAVIA, M.D., Etawah.—*Gardeners' Chronicle.*

GARDEN PESTS.

When the operator has to deal with red spider, a more drastic remedy is necessary, for here fumigating is of little avail. One of the best remedies is Gishurst compound, used in a weak state—say from two to four ounces to a gallon of soft water; the smaller quantity for soft-wooded plants, increasing to the larger quantity for hard-wooded things. An old gardener once gave me the following recipe:—"2½lb. of soft soap, ½lb. of leaf tobacco, ½lb of bitter aloes, and eight gallons of soft water; boil the tobacco-leaf and soft soap in bags of some thin material, to obviate the trouble of straining. To two gallons of the above solution add one of water, which will render it fit for use." Many have found it of great service to pick up odds and ends of gardening information from the fathers of the craft, and one of these, twenty years ago, gave the following as his antidote for green fly:—"1lb. of quassia chips, four gallons of soft water, boil for two or three hours and strain; after boiling, add ½lb. of soft soap." The two foregoing cures are no doubt valuable for green and black fly on roses, fruit trees, &c. It can be applied by means of a soft brush. Either will also destroy mildew, especially the latter mixture. In the case of red spider on vines—and this occurs in almost every vinery, however well managed—the most decided antidote is sulphur. This may be applied by sprinkling dry sulphur on the pipes, or by making a paint of sulphur, clay, and water, with which the pipes shou'd be painted. But care must be taken that the heat be not raised at the same time, for if the pipes are hotter than the hand can bear, fumes dangerous to vegetation will be given off. Red spider and mildew are often very troublesome on peach walls. After the trees have been nailed, it is a good plan to mix 6lb. of sulphur with water, toning it down by the application of soot, and applying it to the wall with the garden engine or syringe. It is best to put it on thickest on the bottom of the tree, so that the vapour from the sulphur can ascend among the foliage.

Thrips and red spider are soon brought into activity by keeping up a hot dry temperature without sufficient ventilation. So in order to avoid thrips and other such pests, the temperature of the house should be well looked after; and, lest any of your amateur readers who are just starting on a floricultural career may not know what thrips is, we may state that it is a very small dark insect, which adheres closely to the underneath surface of the leaf, and is particularly fond of the azalea, but visits other plants. As soon as it is discovered, a war of extermination should be declared and prosecuted with vigour. Green fly is easily detected and dealt with; but it is safer to prevent it by smoking in time than to allow the pest to increase until it becomes a swarm; we can safely state that imperfect ventilation and drought have more to do with the appearance and establishment of these pests than any other causes.—R. D.—*Field.*

QUININE AND HOMOQUININE.*

BY O. HESSE.

I.—Quinine.

The question, formerly raised repeatedly, whether quinine occurs in other barks than those of the genus *Cinchona*, I was able to answer in the affirmative in 1871, when I showed that a bark at that time coming into commerce and erroneously sent out as a cinchona bark,—the China cuprea, which we now know to be derived from *Remijia pedunculata*,—actually contained this alkaloid.† My priority in this discovery has indeed been contested, in that J. E. Howard has stated‡ that already in 1857 he had observed this bark in the London market and found it to contain quinine, although he had published nothing respecting it. But since Howard only a short time previously (November,

* From the *Annalen der Chemie*, cexxv., 95.

† *Berichte*, iv., 818.

‡ *Neues Jahrbuch f. Pharm.*, xxxvi., 296; Flückiger, 'Die Chinarinden,' 1883, 43.

1869) had afresh affirmed to the quinologist Weddell* the experimental law at that time generally held to be correct, that the cinchona alkaloids were peculiar to the cinchonas only, it may be assumed that Howard first had his attention drawn to the presence of quiniue in the bark in question by my discovery, which Flückiger had communicated to him privately.

Far more important than this point is the question whether the alkaloid of cuprea bark then spoken of as quinine was quinine, or only an alkaloid similar to it, homoquinine. Notwithstanding that at the time I found the alkaloid in question to correspond in every respect with quinine obtained from true cinchona bark, I have once more examined the original cuprea bark in connection with my experiments upon homoquinine, the former results being confirmed most completely. Subsequently, also, it was pointed out by me that in cuprea bark quinine is not accompanied by cinchonidine, which has equally been since confirmed by D. Howard and others. On the other hand, according to my observation, quinine is always present in cuprea bark, although the quantity is sometimes relatively very small.

The constant occurrence of quinine in cuprea bark and the persistent absence from it of cinchonidine is so far of special interest that it has been assumed in several quarters, especially by J. E. Howard,† that the plants in their development and growth are capable of converting quinine and cinchonidine into one another. Of course in order to make this conversion preceptible certain influences on the development of the plants or their cultivation at different altitudes are required. Nevertheless, the assumption of such a change as this during the development and growth of the plant proves faulty, since if such a conversion actually took place under the conditions named, it would certainly be possible to discover a sample of cuprea bark in which at least traces of cinchonidine would be present.

Although I am in the position to detect the smallest traces of cinchonidine with quinine, all the experiments made in this direction with cuprea bark, as well as with quinine obtained from that bark, have remained without success, a result that justifies me in saying that the formation of the quinine within the plant takes place quite independently of the cinchonidine.

On account of the absence of cinchonidine it is very easy to prepare pure quinine sulphate from cuprea bark. This has normally, whilst yet unefflouresced, the composition represented by the formula $(C_{20}H_{24}N_2O_2)_2, SO_4H_2 + 8\ H_2O$, like the similarly pure salt obtainable from cinchona barks.‡ The possibility is not, however, excluded that the commercial sulphate obtained from cuprea bark may contain somewhat less than eight molecules of water of crystallization, not only because it has effloreseed more or less, but also because it contains an admixture of homoquiniue.

Uebersicht d. Cinchonen, Weddell, 7.

† *Pharm. Journal*, [3], xiii., 1013.

‡ With respect to the remark of Flückiger upon this salt ('Die Chinarinden,' 1883, p. 55), that "it is not established whether this salt contains seven or eight molecules of water of crystallization, or possibly a quantity lying between the two," I may say that more than twenty years since (*Annalen*, cxix., 361) it was shown by Jobst and myself that the formula $(C_{20}H_{24}N_2O_2)_2, SO_4H_2 \times 7H_2O$, for quinine sulphate, is incorrect. On the other hand, it is not so easy to say whether the sulphate in question contains seven and a half or eight molecules of H_2O. A series of experiments, however, carried out by me with every precaution, showed that pure unefflouresced sulphate may actually contain eight molecules of water of crystallization. In that case the formula attributed to quinine sulphate by Robiquet about fifty years ago would be correct. Undoubtedly the commercial sulphate may contain generally less water than is required by the formula $(C_{20}H_{24}N_2O_2)_2, SO_4H_2 \times 8\ H_2O$, and for this reason, that in manufacturing operations it is almost impossible to prepare it dry and avoid at the same time the occurrence of a partial efflorescence of the salt. Quite apart from the fact that in certain quarters a smaller amount of water (for instance, 14·4 per cent) in quinine sulphate is required, it should not be overlooked that a commercial sulphate corresponding to the legally prescribed tests of the German Pharmacopœia may sometimes contain quite a considerable quantity of cinchonidine sulphate (*Annalen*, ccv., 222), upon which a deficiency in water of crystallization may equally depend.

II.—Homoquinine.

The occurrence in cuprea bark of a special alkaloid, similar in many respects to quinine, was announced simultaneously, in December, 1881, by D. Howard and Hodgkin,* Paul and Cownley,† and G. Whiffen,‡ the alkaloid being named by the first two chemists "homoquinine," and by Whiffen "ultraquinine." The name "cupreine" has also been suggested for it. This same alkaloid was also observed by one of my colleagues a year earlier; but he considered it to be cinchonidine until June, 1881, when he became aware of the error.

According to Tod the alkaloid in question first appeared in cuprea bark in September, 1880, but only in a few specimens of bark; its occurrence first became almost general in May, 1881. The amount of homoquinine in the bark in many cases reached 0·3 per cent, in some 0·5 to 0·6 per cent. According to Whiffen the cuprea bark examined shortly before the publication referred to contained 0·1 to 0·8 per cent of the alkaloid, and he believed that in greater or less quantity it was to be met with in every cuprea bark. Paul and Cownley first observed it very frequently four months before their communication (consequently first in August, 1881). D. Howard, who appears not to have observed it so frequently as Paul and Cownley, states that the quantity of homoquinine in the barks in question amounted to about 10 per cent of their quinine contents, consequently to about 0·2 per cent. Finally to complete the history of our alkaloid it may be mentioned that Wood and Barret§ were unable to observe this alkaloid in several hundred specimens of cuprea bark which they examined specially for the purpose, and they believed that it might be a compound of quinine with conchinine.

With respect to this latter point, my examination of the alkaloid prepared by Tod, as well as of some kindly supplied to me by Paul and Cownley, has shown that this material is free from conchinine. Moreover the statement made by Whiffen, as well as those of Howard and Hodgkin, point to the same conclusion, so that the opinion of Wood and Barret referred to would appear to be without support, quite apart from the fact that I have been unable to obtain any such compound of quinine and conchinine in working according to the directions originally given by those chemists.

All the above-named chemists who have indicated the existence of homoquinine in one way or another are unanimous that the alkaloid in question forms with sulphuric acid a neutral salt rather difficulty soluble in cold water; it is presumed consequently that it would be necessarily mixed with quinine sulphate prepared from the particular bark, since it would not be separated or altered in any way during the manufacture of quinine.

According to my experience the best method of separating homoquinine from such a mixture is by dissolving it in dilute sulphuric acid, precipitating the alkaloids with ammonia and at once shaking them out with ether, from which after a short time the homoquinine separates out in crystals. The crystallised homoquinine, after being separated as completely as possible from the mother-liquor, is redissolved in dilute sulphuric acid, and again precipitated with ammonia and taken up with ether, which quickly deposits the alkaloid in crystals. This operation is repeated as often as may be necessary, but generally a second recrystallization of the base in this way suffices to separate any admixture of quinine.

On a previous occasion,‖ I had, upon the basis of the results of analyses I. and II., which were before me at the time, represented homoquinine by the formula $C_{19}H_{22}N_2O_2$. But in the course of this investigation it has given weighty evidence in favour of the formula $C_{20}H_{24}N_2O_2$, with which, moreover, analysis IV., made by me only recently with well crystallized material, corresponds very well. Before analysis the substance was dried at 120° to 125° C.; it then gave:—

From ether containing water homoquinine separates, if undisturbed, partly in concentrically grouped needles, partly in stout decided prisms, derived from the rhombic system, terminating at the ends in a dome, the crystals being sometimes isolated and sometimes a few concentrically aggregated together. In a disturbed crystallization, on the other hand, according to the degree of concentration of the solution, either a sandy powder or a crystallization consisting of delicate lamellæ is obtained. In all cases it contains water of crystallization, the quantity varying between 2 and 2½ molecules, a part of which is readily given off at 80° to 100° C., and the remainder first at 120° to 125° C.

Crystals of homoquinine exposed to the air gradually become dull through efflorescence; in the more compact crystals, however, the amount of water never falls below 10 per cent.* They can be exposed directly to a temperature of 100° C. without any fear that they will fuse, like, for instance, crystallized quinine trihydrate. At that temperature the alkaloid loses only a portion of its water of crystallization; it first melts at 170° C., forming, upon cooling, a colourless, amorphous mass.

Homoquinine dissolves in ether with somewhat more difficulty than quinine; its solution does not gelatinize upon evaporation of the ether, but crystallizes up to the last drops, if the ether be absolutely free from alcohol. In chloroform it dissolves readily, but with more difficulty in benzol and very slightly in light petroleum spirit. Alcohol dissolves it freely and leaves it upon evaporation in the amorphous form.

The alcoholic solution of homoquinine tastes intensely bitter and has a strongly basic reaction; it neutralizes hydrochloric and sulphuric acids perfectly. Its solution in an excess of dilute sulphuric acid shows a blue fluorescence, which is dispelled by sodium chloride and other haloid salts. Hydrochloric acid also removes this appearance, and a solution of the base in hydrochloric acid shows no fluorescence. These solutions rotate the plane of polarized light to the left; they give upon the addition of chlorine water or hypochlorite of lime and excess of ammonia a dark green colour, like quinine.

With acids homoquinine forms neutral and acid salts, which, so far as they have up to the present been examined, correspond in their behaviour towards precipitants, such as sodium hydrate and carbonate and ammonia, with the corresponding quinine salts; on the other hand, they differ from them in their form and partially in their greater solubility. On account of insufficiency of material I have only been able to deal at all exhaustively with the following salts:—

Neutral Hydrochlorate of Homoquinine is obtained by neutralization of an alcoholic solution of the alkaloid with hydrochloric acid. Upon evaporation of this solution an amorphous residue is left that dissolves readily in water. The aqueous solution leaves again upon spontaneous evaporation an amorphous residue.

Acid Hydrochlorate of Homoquinine is obtained upon adding some hydrochloric acid to a concentrated aqueous solution of the neutral hydrochlorate; the acid hydrochlorate separates at once in stout colourless prisms, which dissolve pretty freely in water, but less readily in hydrochloric acid.

Acid Chloroplatinate of Homoquinine.—Upon mixing an aqueous solution of the previous salt with platinum solution a pale yellow flocculent precipitate results, which almost immediately is re-arranged in small orange-red prisms. The salt contains water of crystallization that is first given off at 120° C.

Hydrosulphocyanide of Homoquinine is obtained upon mixing a solution of the neutral hydrochlorate with potassium cyanide. It is amorphous, dissolves slightly in cold water, but more freely in hot water and in alcohol.

Neutral Sulphate of Homoquinine is obtained upon saturation of hot dilute sulphuric acid with the base. Upon cooling of the solution the sulphate crystallizes in short six-sided colourless prisms, which being very brittle are broken more or less in collection. The salt dissolves in about thirty parts of boiling water, very slightly in cold water, freely in boiling alcohol, and is nearly insoluble in chloroform and ether.

Samples prepared on different occasions gave upon analysis the following results:—

I. 0·2190 gram gave at 120° C. 0·0333 H_2O.
II. 0·4848 gram gave at 120° C. 0·0608 H_2O.
III. 0·3300 gram gave at 120° C. 0·0420 H_2O. and 0·0925 SO_4Ba.
IV. 0·2243 gram gave at 120° C. 0·0293 H_2O.

	Calculated for	Found.			
	$(C_{20}H_{24}N_2O_2)_2SO_4H_2+6H_2O$.	I.	II.	III.	IV.
H_2O	12·64	13·37	12·50	12·85	13·01
SO_3	9·37	—	—	9·62	—

The crystals of this salt effloresce superficially in air, and become consequently dull; the loss of water is, however, not worth notice. Even after a considerable time the water of crystallization amounts still to 12·50 per cent. On the other hand, quinine sulphate exposed to exactly the same conditions would at the end of a couple of hours have fallen to a powder, and would then contain only 4·2 to 4·6 per cent of water. If the two sulphates, dehydrated at 120° C., be exposed to moist air, the quinine sulphate rapidly takes up 4 per cent of water, but the homoquinine almost three times as much, namely, 11 to 12 per cent.

It was of especial interest to ascertain the behaviour of homoquinine to polarized light, since the alkaloid on account of this behaviour received from Whiffen the name "ultraquinine." According to Whiffen this sulphate in acid solution showed $(a)^\circ = -221^\circ$, whilst quinine sulphate only showed $(a)^\circ = -196^\circ$. Of the water of crystallization of the two sulphates, in which they certainly differ from each other, Whiffen makes no mention, so that it is quite possible that the difference in question was purely dependent upon the different quantities of water of crystallization which they contain.

In my experiments the amount of water of crystallization was first exactly estimated, and then a quantity of each of the hydrated sulphates corresponding to 1·25 gram of anhydrous salt was dissolved in 10 c.c. of normal hydrochloric acid. These solutions were then each diluted with water up to 25 c.c., and finally examined at $t=50^\circ$ and $l=220$, the deviation being sometimes determined first by means of the quinine solution, and then this solution changed for the homoquinine solution, and sometimes the order being reversed. In this way it was ascertained that *the two solutions did not differ from one another in respect to their optical behaviour.* In an average of thirty determinations $(a)=25·92^\circ$, which gives for the anhydrous sulphate $(a)^\circ = -235·6^\circ$.

Neutral Tartrate of Homoquinine is obtained by mixing a hot aqueous solution of the sulphate with solution of rochelle salt. It forms delicate white concentrically grouped needles, which dissolve with some difficulty in hot water and are very slightly soluble in cold. The composition of the salt is represented by the formula:—

$$(C_{20}H_{24}N_2O_2)_2, C_4H_6O_6+2H_2O.$$

0·3305 gram of air-dried substance gave at 120° C. 0·014 H_2O.

* The substance obtained in delicate lamellæ effloresces very rapidly, and frequently after a few hours the quantity of water of crystallization amounts to only about 6 per cent. This phenomenon may probably be partially due to the larger surface which the lamellæ have as compared with the more compact crystals.

	Calculated.	Found.
H_2O	4·31 . .	4·23

The tartrate dried at 120° C, takes up from moist air only 1 molecule of H_2O; it has then the same percentage composition as neutral tartrate of quinine.

This dissimilar composition of the two tartrates must not be overlooked in the estimation of quinine optically by the method of Oudemans, jun,* otherwise, up to about 4 per cent of cinchonidine sulphate might be "found" in a quinine sulphate obtained from cuprea bark in which not a trace was present. This mistake may, however, be easily avoided, by previously determining the amount of water in the tartrate, and as I have done in my optical quinine test,† starting from the anhydrous salt.

III.—Conversion of Homoquinine into Quinine.

Some observations which I made during the investigation of cuprea bark agreed pretty well with the presumption that under certain conditions homoquinine might change into quinine. To ascertain these conditions I first heated the alkaloid to 100° C. with dilute hydrochloric or sulphuric acid, sometimes in open vessels and sometimes in closed tubes, but without result. Hydrochloric acid of specific gravity 1·125 acted no better; but upon heating the latter solution some hours to 140° C., methyl chloride and apoquinine were formed, as with quinine. Nevertheless, I was unable to separate quinine from this solution by means of ammonia before this formation took place. If, however, soda ley were used for the precipitation of the alkaloid, a certain quantity of quinine now resulted. In consequence of this observation I was now able, by repeated precipitations with soda ley, shaking the precipitates with ether, and this solution with very dilute sulphuric acid, to convert homoquinine completely into quinine. The conversion is essentially accelerated by heating the base with soda ley, a previous heating of the acid solution being thereby made unnecessary.

From the quinine obtained through conversion of homoquinine the neutral sulphate was prepared, which gave—

I. 0·5425 gram at 120° 0·0893 H_2O.
II. 0·7320 gram at 103° 0·1170 H_2O.
III. 0·4625 gram at 120° 0·0720 H_2O.

Calculated for	Found		
$(C_{20}H_{24}N_2O_2)_2,SO_4H_2+8H_2O$	I.	II.	III.
H_2O. . . . 16·17	16·46	15·95	15·54

This salt effloresced rapidly in dry air and then contained still 2 molecules of H_2O. On the other hand, the dried sulphate quickly took up 4 to 4·6 per cent of water.

In other respects also, no difference could be recognized from the known pure sulphate.

IV.—Concluding Remarks.

The foregoing results justify the conclusion that Barret and Wood in their investigation converted the homoquinine into quinine and that it thus escaped observation by them. I myself also had previously fruitlessly endeavoured to prepare the alkaloid in question from cuprea bark. It was only after a series of English chemists had simultaneously affirmed the existence of homoquinine that I felt I ought to drop my doubts as to the peculiarity of the alkaloid, which was at any rate first prepared by Tod; but up to that time I had considered the substance in question to be none other than *crystallized quinine*.

Upon the grounds stated my original opinion as to the nature of this substance might still be correct. It is true that at present I have not yet succeeded in preparing homoquinine from cinchona bark, and it may be there is no present prospect that it is obtainable from that bark, so that this substance may still pass as characteristic of the *Remijia pedunculata*, which yields the cuprea bark. But I might maintain to the contrary that I formerly had the opportunity of being able to point out that quinine under certain conditions would become modified, in that it passed into the anhydride, and that this substance also *behaved as a special alkaloid*. At that time also I succeeded in reconverting this substance into ordinary quinine through prolonged treatment with dilute sulphuric acid, though not through precipitation with soda lye.‡

Besides this modification of quinine there exists at least one more, which forms with sulphuric acid a neutral sulphate that separates from a hot aqueous solution as a jelly, only subsequently assuming the crystalline form.* I was formerly inclined to place this peculiarity of the sulphate in question to the account of a colouring substance, concerning which not much was known. Nevertheless, exactly those solutions from which quinine sulphate separates at first in a gelatinous form are so little coloured that the cause of the gelatinization might far rather be sought in the absence of colouring matter. I may also add that in the cases mentioned, if the alkaloid be taken up in ether, the ethereal solution gelatinizes relatively easily. These peculiarities of the alkaloid disappear, however, most surely if the sulphuric acid solution be subjected to a prolonged boiling.

The most important results of the foregoing investigations may be brought together in the following propositions:—

(1.) Homoquinine is a modification of quinine.

(2.) Cuprea bark in many cases contains this modification together with quinine.

(3.) Several modifications of quinine exist, which by suitable treatment pass into ordinary quinine.—*Pharmaceutical Journal.*

WOODS AND RAINFALL.

The fact that a spring is often seen to increase in volume during the period in which a wood is growing, and ceasing to flow on the same being cut down, at the same time that the soil, when it is covered with trees, is usually in a dry state, has frequently been mooted, and a variety of reasons adduced for this peculiar feature. I therefore venture to note down my own observations, taken in various parts. Surface-soil will be dry owing to the root absorbing as much water or nearly as it can hold between its organic particles. What cannot be retained by the soil nor be utilised by the roots during its downward progress reaches lower and impervious strata, and will there remain to form springs may be, or it may rise to a higher level by natural increase from snow and rain, and then flow over through pervious strata to lower levels such as those of brooks and rivers.

On bare land, although there is nothing in the way of roots to absorb moisture, if we except the roots of herbage, the surface-water runs on to lower levels, if the surface is hard, or forms pools and marshy places, and in stiff soils remains for lengthened periods, during those periods of the year when the sun has but little evaporating effect on water. In the hotter months the evaporation from bare land is much greater than is possible in a wood, the soil of which is shaded by the trees, and therefore rains falling at that period have not time to soak into the land, but are rapidly evaporated by the sun-heat, and carried elsewhere in the form of vapour. Perhaps bare, light soils overlying gravel or greensand, lose less by evaporation than the former, as the descent of rain is much quicker to depths beyond the reach of the sun's power.

Where forests abound floods are much rarer in the main streams, provided the banks are sufficiently high and strong, and that there is care taken that no silting up occurs from any cause, thereby raising the bottom of the stream in places, and so causing a want of room for large quantities of water. Where snow remains on hill tops, and then suddenly melts in June and July, floods are then the most difficult to avoid, or to control, although forests may clothe the lower portions of the hills and line the streams. But if such hills—when the altitude admits of its being done—were planted to their tops, the greatest risk would be averted, as the melting of the snow would be gradual, and the consequent rush of water after heavy summer downfalls would also be much less rapid. Forest ground evaporates therefore less than bare ground, and the trees on it consume much water by their roots and absorb also a little by their leaves in summer time. In winter the action of trees on the water falling on the land becomes more controlled by the nature of the soil, its slope, and the composition of the underlying strata. Trees at that season exert the minimum of direct influence through root action, and water either sinks slowly, as in heavy soils and in partially previous strata, or rapidly in those of an opposite nature, and much finds its way by artificial and natural channels to rivers,

* *Annalen*, clxvi., 262.

&c. Failing these natural and artificial means of clearing land of the moisture that in one or another form descends on it, it gets only partially dried by the action of tree roots, assisted by evaporation from its surface during the hotter periods of the year.

In this way forests act as conservators of water in so far as they prevent a too rapid evaporation, but the trees themselves part with great quantities which has been drawn by their roots from the soil, and which is lost in the air by a drying-out process going on in the leaves. Their own requirements in building up the tree growths of stem, roots and foliage represent an immense amount of water and dew, and it is only the surplus remaining which finds its way to the streams; but this flowing away gradually and in reduced quantity than is the case from bare soil, is therefore less liable to cause floods, except in such exceptional instances as have been alluded to.

The dampness felt in dense or even moderately dense woods is not so much due to any locked up moisture in the land itself as to the confined cool moist air, a condition that is owing mainly to the shade of the foliage hindering the sun's heat from penetrating to the stratum of air near the ground level. Higher up, near the tops of the trees, it is of a pleasanter and more buoyant nature. In windy weather this cool moist feel in the air is much lessened, or else entirely absent, the moisture itself being carried through the wood by the action of the wind, and is replaced by the drier, or colder, or may be warmer air, from outside the wood. This condition of the air within a wood will account for the prevalence of dew on the herbage early in the day, and up to mid-day, and in denser parts throughout the day, when the air circulation is gentle.—M. A.—*Gardeners' Chronicle.*

TEA CULTURE IN NATAL.

During the past few years, I have heard much of tea growing in Natal on a small scale, which could only be termed garden culture. Natal is, however, indebted to Mr. J. Leige Hulett, M.L.C., for striking out boldly on a large scale to prove the adaptability of certain districts of the colony for this industry, which, I am pleased to say, is an undisputed success. Mr. Hulett's plantation is situated in the Nonoti district, Victoria County, N.E. of the town of Durban, connected in part by railway. The land is not in any way special, but merely the ordinary run of coast land, of which thousands of acres are available. Mr. Hulett has compared his crop with an estimated yield in India, where 640lb. per acre is given as the yield in the tenth year. Of his 1883 yield he says:—"My picking area has been this past season as follows:—About half an acre seven years old (imported hybrid plants): 4½ acres, first year 1881; 27 acres, first year 1882. According to the above estimate I should have manufactured —½ an acre. 240lb.; 4½ acres, at 100lb. per acre, 720lb.; 27 acres, at 40lb. per acre, 1,080lb.; or total, 2,040lb. Instead of which, my yield for the season will reach 9,000lb. of marketable tea."

When I left Natal at the end of last June, Mr. Hulett had 75 acres of tea under cultivation. The cost of culture of land is not under any circumstances over £5 per acre per annum; this includes weeding, manuring, priming, tools, &c., which, allowing 800lb. of tea per acre (when five years old), will give 1½d. per lb. for the annual growth of the tea. The cost of picking comes to 2¼d. per lb. of made or dry tea; cost of rolling and drying, 2¼d. This gives 6d. per lb. total cost of growing and manufacturing, exclusive of interest on capital outlay. Mr. Hulett further remarks, "Had I possessed a rolling mill and drying furnace the cost would have been considerably lessened; say, picking and making, to 3d. per lb., or 4½d. in all;" and he believes that tea can be grown in Natal to pay all expenses at 8lb. per lb.; but that would not leave much margin. Any company or private person could make it pay at 10d. or 1s. per lb. for exportation. He does not advise the employment of Chinamen, as Kaffirs can be taught easily to pick the leaves.

My own opinion is that an enterprise is before the colony well adapted to the requirements of those possessing small capital, say from £500 upwards, especially when ten or twelve can grow for a central factory. "Indeed," says Mr. Hulett, "I am quite prepared to purchase this leaf in the green state, and give 3d. per lb. for it, direct from the tree, until export becomes a necessity."

At the present Industrial Exhibition (Jan. 1884) a gold medal was offered for the best 10lb. of marketable tea, and from the Natal Agricultural, Horticultrial and Industrial Exhibition Report it appears that the judges could not decide between exhibits by Mr. Hulett and Mr. Lyle until the tea was liquored, when Mr. Lyle took the prize, and Mr. Hulett was awarded a silver medal for the best collection of teas. The judges further reported that the tea shown, although not all liquored, seemed to be very good; and the number of samples (five) made them hopeful that this comparatively new industry would yet take a prominent place among the productions of the colony.

The demand for tea in Natal, the Cape Colony, Orange Free State, and Transvaal is great; consequently there will for some years to come be a ready market for home consumption, duty being about sixpence per pound on imported tea.

Just previous to leaving Natal, Mr. Hulett forwarded me some samples, marked Pekoe 1, 2, 3; and I obtained a sample of very coarse, rough tea (used for mixing) from his local agent in Durban. These samples I brought home in my portmanteau; they were not in any way protected, further than being wrapped in paper; and, moreover, were frequently exhibited and sampled on the voyage, which may account in part for the broken, irregular leaf alluded to in the following report. I may add that Mr Hulett told me that he was well aware that experience was wanting on his part to prepare the leaf properly, and that he was anxious to obtain an expert in tea manufacture to instruct him. It will be seen that, in spite of these drawbacks, Mr. Hulett has practically surmounted the difficulties attendant on a new industry.

Appended is a copy of the report above referred to:—

I have put the samples of South African teas into liquor, and make them very decent value, as follows: No. 1 sample, 1s. 5d.; No. 3 sample, 1s. 6d. to 1s. 7d.; No. 4 sample, 2s. 2d. to 2s. 3d.; and the very rough sample, 8d. to 9d.; these prices are without the duty. If the samples were not so small or broken in the leaf, they would be of more value. I have also had the opinion of one of the oldest and most respectable brokers upon the samples, and he thinks with me. Tea from South Africa is a novelty, and if it can be produced without being so broken in the leaf, it would be worth more in the London market.—C. Dight, London, Sept. 1, 1884.

I trust the foregoing note may be of some interest, and I append my name and address, as I am willing to afford all the information possible.—MORTON GREEN.—*Field.*

COLORLESS CEMENT.—The following recipe is said to produce a perfectly colorless cement:—In an air-tight bottle 75 grams of indiarubber cut into little pieces, are mixed with 60 grams of chloroform. After complete solution of indiarubber, 15 grams of mastic are added, and the mixture warmed for eight days till the latter is dissolved also.—*Leder-markt.*

TOBACCO ON THE NILGIRIS.—The *Madras Mail* writes:—"In the present depression which unfortunately characterises the market for all Nilgiri-grown produce, the planter would be well-advised to turn his attention rather to the revival of the cultivation of old and established favorites, known to be acclimatised, than to look to remote places for new and untried products. Tobacco was grown, we are told, very many years ago by the Badagas, but was adandoned when the Government monopoly in that article was abolished. Local native poetry abounds in allusions to the fragrant weed; and tradition goes so far as to assert that tobacco cultivation was an established industry on the hills long before the period of the introduction of the leaf to Europe from the new Continent. The quality of the Nilgiri-grown tobacco at that early period, is said to have been excellent, though the curing must have been by very primitive and imperfect processes. Coimbatore, whence the Nilgiri tobacco was probably derived, is a tobacco producing district, where the saltpetre impregnated soil offers the most favourable conditions for its growth, and confers upon the leaf a good burning quality. Within the past few years an impetus has been given to enlarged production in Coimbatore, by the establishment of cigar factories in adjoining districts, and hence the extent of land brought under cultivation has been increasing at the rate of 500 acres per annum."

PAPER FROM TOBACCO.—A man at Waverly, Mass., has discovered a process for utilizing the stalks and stems of the tobacco plant as a substitute for wood pulp in the manufacture of paper. Samples of paper made by this process under unfavorable conditions show comparatively few defects, and the strength is said to have been successfully tested by lifting a 100-pound boy on a single broad sheet. A great point in the manufacture of the pulp is the fact that only the ordinary machinery, found in every paper mill, is required, while wood has to be skinned, strapped, relieved of knots and rotten parts, and grated. The average quality of wood used loses from sixty to eighty per cent in waste; tobacco stalk, however, shows a waste of only five per cent.—*Independent Journal.*

RED SPIDER.—If your correspondent G. B. H. will do as follows, he will get rid of his red spider. Let him wash the walls with boiling water, brush over the stems of his peach trees with a stiff brush and water at 130°, in which a large lump of common yellow soap has been dissolved. I have done this with success.—R. M. J. TEIL (Newton Abbot, Devonshire).

—— The following is a good recipe for destroying this pest. Put about a pint of guano in the evaporating troughs, then have the pipes made very hot; this will cause the ammonia to rise, which will soon destroy both spider and thrips. This should be done every evening for a week; after this the peach trees should be syringed with clean water twice a day until the leaves are perfectly clean. I have done this with the desired effect, both in peach houses and vineries.—R. N.

—— Boil one pound of sulphur and one pound of hot lime in a gallon of water twenty minutes, bottle it, and when wanted for use, put one gill into three gallons of water, and syringe trees with it. It will not hurt fruit or foliage, whether washed off or not. Hop growers should make a note of this, as it is equally effective against blight or mildew—SUBSCRIBER.—*Field.*

EUCALYPTUS AND MALARIA.—In a letter to the *British Medical Journal* (Sept. 27th), Dr. L. Aitken, of Rome, denies the correctness of a statement that has been repeated over and over again, namely, that the sanitary state of the neighbourhood of that city has been improved by the planting of eucalyptus trees. Except at Tre Fontane, he says, where the unpaid labour of monks and convicts keeps the trees alive, the experiment of planting the Campagna has proved a costly failure, only three or four per cent of the trees planted under the conditions attending the plantation of other young forest trees having survived. Even at Tre Fontane the Government has found it necessary to restrict the amount of convict labour which it at first placed at the disposal of the Trappist monks for planting operations, in consequence of the sickness among the warders and convicts. The monks themselves, too, are known still to succumb to malaria, though Dr. Aitken more than hints that the whole truth is not made public, lest it should affect the sale of the eucalyptus elixir which is prepared at the monastery and adds materially to its revenue. Dr. Aitken does not deny that the deaths from severe malarial fevers have decreased during the last year or two, but apart from the fact that this may be due to fluctuations in the intensity of the malarial poison, he is inclined to attribute any slight improvement which may be claimed quite as much to the necessary subsoil draining and preparation of the ground as to any influence of the young gum trees.—*Pharmaceutical Journal*, Oct. 11th

DAMMER TREE AND PINEY TALLOW.—A letter from Major I. Campbell Walker, Conservator of Forests, Southern Circle, to the Secretary to the Board of Revenue, dated Madras, 6th August 1884, states that the following specimens were sent direct to the India Office from Malabar and South Canara:—*Malabar*—Samples of the ripe fruit of both species of *Vateria* in spirit, as well as specimens of resin and the dried fruit and kernels. *South Canara*—Dried fruits, kernels, tallow and gum resin of dammer tree (*Vateria Malabarica*). The Collector of Malabar states that 40 lb. of the kernels of each species of *Vateria, Perum* and *Chera* (large and small) *Piney* were reduced to powder and boiled for eight hours, but that not a particle of fatty, oily, or resinous matter appeared. As regards the manufacture of candles from Piney resin, the Collector of Malabar reports that it "is not now carried on in Calicut, or any other town or village in Malabar," and that "the industry appears to be extinct." The Collector of South Canara says, "Candles made from the resin are not known here." The Government order on this letter is as follows:—The Government observe that the "tallow" mentioned by Mr. Thiselton Dyer is said to be made from the fruit, not from the kernel as assumed by the Collector of Malabar. The Collector of South Canara appears to have forwarded some "tallow," but it is not stated how this was manufactured. As regards candles, page 447 of Drury's "Useful Plants of India" may be consulted. The Government desire that further inquiry and experiment may be made on both points.

THE EDINBURGH FORESTRY EXHIBITION.—Mr. Alexander's collection of exhibits, as already mentioned by us, was chiefly handed over to the Committee connected with "The New School and Museum of Forestry in Edinburgh," but specimens were also given to the Pharmaceutical Society of London; Museum of Science and Art, Edinburgh, Oberlin; College, Oberlin, Ohio. The final award list now to hand gives Mr. Alexander the following:—

For general collection, 1st class Gold Medal.
Collection of Photographs &c., 1 Bronze Medal.
,, of Fibres &c., Diploma.
,, of Woods, Commended.
Essay on "The Harvesting and Producing of Cinchona Barks," 1st class Gold Medal—highest award.
Essay on "Insects Injurious to Timber and Forest Trees," with specimens—Silver Medal.

Mr. Alexander has therefore every reason to be well-pleased with the honours he has received; for, many of the countries represented have not done so well. The following from the *Scotsman* gives an accouut of the closing of the Exhibition:—

It is estimated that nearly 500,000 people have visited the exhibition. As to the financial results, it is believed that there is likely to be a deficit of not less than, in all probability, between £500 and £1,000. The accounts have not yet been made up, and, accordingly, no exact statement can be given; but the above estimate is believed to be only too well grounded, and certainly not over the amount of the deficit that may be looked for when everything now due has been paid off. This deficit is attributes chiefly to the heavy expenditure that has been necesd ary to the carrying on of the Exhibition, with all it attractions. The buildings, in the first place, cost upwards of £7,000; that of the electric light has been, it is said, about £1,500; and £36 a night has been paid for other illuminations. The promoters of the proposed School and Museum of Forestry have now obtained from the Lawson Seed Company a place for the temporary accommodation of the exhibits that have been promised for the Museum and accordingly, it is understood they do not propose to acquire any considerable portion of the Exhibition buildings. These in the course of a short time will be taken down and removed. With the nucleus of a museum obtained, and with the premises of aid received, hopes are entertained of the establishment of a School of Forestry in Edinburgh. Upwards of forty of the exhibitors have promised considerable and valuable portions of their exhibits for the museum, which will thus acquire specimens from Japan, British Guiana, India and other countries abroad. The Maharajah of Travancore has promised some of his exhibits; and specimens of wood pulp have also been promised. Her Majesty's Woods and Forests will also largely contribute to the Museum; and a great many tools and models from different parts of the country—illustrative of, and connected with, the science of forestry—have also been secured. Among the contributors at Home are the Duke of Buccleuch, the Duke of Argyll, the Duke of Athole, Sir James Richardson, Mr. Owen, Mr. Oscar Dickson, and other gentlemen. For the establishment of the School and Museum of Forestry, the Committee, at the head of which are Mr. Hutchison of Carlowrie, Colonel Dodds, Dr. Cleghorn, and other gentlemen, are about to make an appeal to gentlemen interested in the subject for their financial requirements.

MINOR PRODUCTS IN THE WEST INDIES.

The *Dominica Dial* of September 20th which reached us by last mail has a leading article on "Minor Products to the Rescue," from which it is of interest to quote as follows :—

On the principle that out of evil sometimes cometh good the present crisis in West Indian sugar affairs may be made the means of a new departure for our agricultural interest. To many of the small property-holders, for whom the present low price of sugar makes impossible the continued cultivation of King Cane, there is absolutely no alternative but a change to those minor products at which it has hitherto been the foolish habit to turn up our noses. Cacao, tobacco, nutmegs, mace, cinnamon, black and white pepper, cloves and various other spices can be grown to perfection in the rich soils of this island. Already the export of cacao, including the large quantities illicitly carried away from the Windward side of the island in French bottoms to Martinique and Guadeloupe, cannot be much less than 1,000,000 lb. Within a very few years to come, with more intelligent skill in pruning and greater knowledge of how to cure this important product, the present outturn will be more than doubled. Another hopeful feature in the agricultural outlook is the arrival for the last three seasons of American speculators in fruit, oranges principally. It is to be regretted that hitherto no trade has sprung up in bananas, of which up to now Jamaica and Central America enjoy the monopoly. But with our millions of banana trees there is no reason why the attention of American fruiterers should not be directed to the untried field of Dominica. Of course regular steam communication and more rapid transit will be necessary, and would follow as a consequence of an extended fruit trade.

After a good deal more i general terms, our contemporary winds up with the following special compliment to the *T. A.* of Ceylon :—

Our subscribers will do us the justice to bear in mind that one of the self-imposed duties of our journalistic career is to inculcate on the mind of the public the necessity for introducing those new products on which information has been published in these columns from time to time. Most of these articles have been taken from the *Tropical Agriculturist*, a serial published at Colombo, Ceylon, and containing valuable information on every subject connected with agriculture in the tropics. It is no exaggeration to say that every planter and proprietor of land in these latitudes should take in and read this valuable work, if he is to be put in possession of information and experience which intimately concern his interests. The number of those who have hitherto taken in the *Tropical Agriculturist* in Dominica is exceedingly limited; but we venture to assure the planters of this island that, whether our projected Agricultural Society is formed or not, they will find in the pages of the excellent publication we allude to inestimable help in choosing those new products to which the necessity of self-preservation compels them to resort.

TEA PLANTING IN CEYLON.

THE HISTORY OF MARIAWATTE; EMBARGO LAID ON CROWN FORESTS: A POLICY WANTED.

The history of this little tea property is interesting. Nearly half a century ago, it was opened as a coffee estate, but, owing to bad management or some other cause, it was at some unknown period in its history abandoned and allowed to grow up into jungle. In that state it remained for some years, when, having fallen into other hands, it was again cleared from the low jungle that had grown up, and once more planted with coffee, but with very indifferent success, though it appears to have yielded crops for a number of years, when it was for the second time abandoned, and once more became a wide waste of woody undergrowth, prominent amidst which was the *lantana*, a foreign shrubby weed of marvellous rapid growth, said to be a great recuperater of worn out soils. This quality would seem to have been given to it in the present case, as long before any manure was applied to the tea on the Mariawattie Estate, it bore heavily. The oldest portion of the hundred acres in bearing is now about six years old, some of it only four. But it is conveniently situated for the cartage of manure, and lies on an undulating site.

If the extension of tea cultivation in this island depended on the acquisition of crown lands, it would have cut a rather sorry figure at this present time. As a matter of fact for every hundred acres of *new* land opened for this cultivation, there are, or will be during this and the coming year, a thousand acres of coffee estate land planted with the new product. Where this can be done with prospect of success, the advantages are many and striking—there is no felling of forest or burning off, all is ready to hand, roads are ready made, drains are cut throughout, coolies' lines are there, manager's bungalow, and, what is of even more importance, a good well built store easily convertible into a tea factory. There was a sale of such a property a few days ago, comprising 420 acres of coffee and jungle, mostly the former, which went for R6,000. The buildings, roads and drains were worth the money, and there was the land sufficient for forming a first class tea plantation thrown in, I may say, for nothing! In a few years the new proprietor will have put money into it which, if judiciously spent, will make it a valuable property. Our Government are trifling with investors of capital in a new tealand in a most unaccountable fashion. A short time ago, the representative of a London capitalist applied for a thousand acres of crown forest very indifferently timbered but of good quality The block was surveyed and advertised for sale, the intending purchaser in the meantime had purchased large quantities of tea seed, and had actually had nurseries laid out on an adjoining block of land which he had previously bought. To his intense surprise and great mortification, a notice appeared in the *Government Gazette* three weeks before the appointed date of sale, stating that the land was withdrawn from public competition, with no reason stated. Upon this the applicant sought an interview with the highest authority in the island, and stated his case, pointing out the hardship and loss the withdrawal of the land would entail. But the Governor was immovable in his resolve, assigning as a reason that it was held back on climatic consideration!* Perhaps you may remember that two years ago or more, one of the Indian Forestry Staff, a Mr. Vincent, came to Ceylon at the request of our Government to report upon the forests of this island. He drew up a very long and well written report, which was afterwards printed, and as you may imagine, it dealt with forest conservancy in every phase. It advised Government in regard to the future care and development of its forests much on the lines of the Indian forestry work, but whilst adopting some portion of Mr. Vincent's report, it has left others untouched, and inasmuch as to the present time no policy has been declared, save in respect of the vast tracts of forests in the north of the island, the home of the elephant and the bear, where all is reserved and properly so. No planter can say what land the Government will sell or what it will retain, so that the public are left in a state of complete ignorance as to where to make their selections.—COR., *Indigo and Tea Planters' Gazette*

PLANTING IN BRITISH BURMA.

(*By an ex Ceylon Planter.*)

NEW PRODUCTS FROM CACAO TO CHESNUTS : NUTMEGS, CARDAMOMS, ARNOTTO, CROTON—PRAISE FOR WILLIAM BROS.—TRAVELLING UNDER DIFFICULTIES!

Tavoy, 13th Oct. 1884.

I am still alive and in splendid health, thank goodness. Since I wrote you last I have done a good deal of hard work and have planted up all my new clearing. What made it more difficult I had to see everything done myself, had a number of men that had to be trained into their work, never having seen such products before, and rather clumsy at their work. However all is planted up, and the work done thoroughly well, and my planties are showing up their little heads nicely. I am now sanguine of success. My clearing would amuse a good many planters. I have planted it

* We have heard that eventually the sale of 400 out of the 1,000 acres was granted to Mr. W. Forsythe, the agent referred to, on his representing to the Governor that his nursery plants would be wasted. The 400 acres are, of course, to be put up to auction sale as usual.—ED.

up in a novel style : when felling, I only cut down the scrub and small trees and left all the rest and burned off sharp ; in doing so saved the roots of a great many trees. The lining was rather difficult, but I persevered and had it all lined in proper form 6 ft. × 6 ft.; then I have my holes cut, good old-fashioned holes 18 inches and well filled in with all the surface soil, only allowing all the scrub to grow up to answer for shade : this mode has answered excellently, and I have a fair cover of shade all over my clearing. In planting out my plants, I had them shaded until they stuck then I had the shade all removed, and they are now bonnie and green and thriving A 1. Of course, I have my troubles : it is not all mild sailing. The little rascal the mole-cricket is the enemy, and I may say the only enemy, to the plants that I am troubled about, he cuts them down about one inch from the ground. The Arabian coffee grows again, but it 's almost death for the Liberian. Well I have kept pegging away and supplied up again and again. I have lots of fine plants, and have supplied up also all sickly plants, and the appearance at present is a good cover—could not be better.

The cacao is very fine and the cricket does not touch them, but they grow here at a great rate. I have cacao 18 inches high already, nice little bushy plants and the soil is excellent : a dark brown loam seems to suit them. I have no wind and am in a valley well protected on all sides. Of course I had my pick of the land and did my best to select what I consider a suitable soil and aspect, etc. Cardamoms have given me some trouble, only I am gaining experience and have hit on their requirements now. Owen's little book assisted me greatly. Tea grows apace at a great rate—could not be better. "Anotta" or "arnotta" splendid. I have arnotta planted for shade in a flat field. Nutmegs coming on beautifully, and I have now mastered them and have no difficulty in germinating them. Teak is a slow grower, and I don't think suited for Tavoy district. Durians are a success, and I have planted this in every seventh line for shade, also jak, common jak and Penang jak, and also other Burmese fruit trees. I have planted them mixed in line for shade every seventh row.

I have succeeded in planting a lot of chesnuts : they will come in handy for tea-boxes. It is a beautiful tree and bears a heavy crop of nuts in Tavoy district. I have a number of rubbers, but will not say anything about them, until I gain more experience gradually with them. Gambiers grow nicely, three varieties : they grow *slow* at first for two years, I am told by foresters. I have a few mangosteens and their growths have been very slow to my idea.

Divi-divi grows slow also, but they are hardy and nice plants. Croton-oil tree, Mr. Holloway's favourite, grows at a great rate, and I have trees three feet high already.

Henaratgoda William & Bros. sent me a lb. of croton-oil tree seed, Brazilian coffee, rubber, cinchona of kinds, and also Acacia, Arabica and Dalbergia Sissoo seed ; they all came in splendid order, nicely packed and by all appearance most carefully selected. I have put them all in, and will report progress by and bye.

By last mail William & Bros. sent me 48 pods of the best cacao ; the pods *were packed as I advised them*, and I am happy to say we have succeeded : 32 pods were as bonnie and fresh as the day they were put in by them ; 14 were a little discolored outside, but the seed quite *sweet* ; two were rather black and discolored but not germinated, only showed a very little.

I can now recommend anyone who wants cacao pods, by all means apply to J. P. William & Bros., Wilhelm's Rube, Henaratgoda, Ceylon. I had out of my 48 pods 1,300 seeds in excellent order, and I trust William Brothers may turn out a patent process of transport to good account. 20 days on the journey, and on the 21st day I had them into the nursery. But my dear "Brother Planter," you must avail yourself of the parcel post. Agents and steamship agents are a queer lot, and have a happy knack of not understanding you. *No, no*, you cannot put them out of their own trust. If you advise anything original, you must be a fool and cannot explain yourself. I have a maund of tea seed kicking about somewhere, and goodness knows when I am to hear of it ; it was booked at the same time as my *cacao seeds*. Invoice received, but no box of seeds, nowhere to be found ; perhaps it 's rotting in Madras.

I bought all the Nat-ya-doung plants from Capt. Schwolly. He has left ; he found Nat-ya-doung to be exactly as I said in my report, not fit for the products he had given the Government a guarantee to cultivate.

I left this in the middle of July en route for Nat-ya-doung to remove part of my plants with 28 Ramasamis. Such a time we had ! It was in the full burst of the S. W. monsoon. For 15 miles the road was in fine order, I may say 17 miles until we reached Mr. Wallace's spacious wire bridge near Thatchory, and after we left the splendid wire bridge, for other sixty miles. Fancy yourself, Mr. Editor, starting from Colombo to go to Kandy with no road, only a track, and all the bamboo bridges broken down and no place to put down your old head ! I had to look out for a soft plank and woke up, dreaming of climbing up Ardallie hill, saw T. M. cracking his thumbs with his beaming cheery face, singing out, "Hill-o Watson, *foo* are you man?" My coolies came on manfully and cheerily, and, after a lot of cannie engineering, we reached Bubble Town and Nat-ya-doung. The three coolies, poor fellows, in charge of the nurseries were very glad to see me and ran to bring coolies in Burmese "murgies." We were well pumped out and tired. I found the plants in firstrate order, some of the Liberian coffee three feet high, tea, etc., also Ceará rubber 10 feet high and fruit out on, it, cardamoms well forward; also Arabian coffee, orange trees and other fruit trees.. The following day we started and packed up plants I had larger baskets made for the purpose but not enough ; the balance we packed in sacks and coodies. It rained awfully. We stopped the night and started early next morning. Now comes the rub ; we could not cross the river, too high by far; however Nat-ya-doung postmaster (a Tamil) came to our rescue and offered to pilot us a new route. We started at once and came on all right until we came to the first stream ; it was rapid and deep. A few of the best of the coolies got across hand on to land, when one fellow, a chetty cartman, went down the stream. The bushel floated and was rescued, but poor chetty was losing ground fast. I plunged in and dragged him out by his wrist. He was more afraid than hurt and was quite useless for that day. We reached the large river, but could not pass—too much water by far. The postmaster turned back to a Karen's house and the owner offered to pilot us to another temporary bridge of his for some pices. We got over with some difficulty and proceeded along in pouring rain until we came near the sea. We took the sea route as the rivers are broader, and when the tide is full there is little current. The coolies walked into the larger river but turned back again to me saying that they could not pass. I selected the tallest man, and I myself am a 6-footer and took him by the hand, and as the tide happened to be full there was no current, so we reached the other side nicely, but it was so deep that I had to hold up my watch by my left hand. The whole lot took courage and came wadding along. We reached the sea and had to wait until the tide receded, and we passed the other large river in safety. We reached *Ya-Na* at last and

stopped there for the night at the Ponjie Chey in a "Zat," something like a cattle-shed. I don't refer to Logie's cattle-sheds, but to a poor Sinhalese man's shed. Next day we started for Siog-a-bin and reached a nice little dāk bungalow P. W. D. Got up early and reached Thatchay: had comfortable quarters, where Assistant Magistrate came to me, poor good soul, with tea, biscuits, butter and a variety of fruits, the "g'omen" Wallah turned up, and we had a chat over my adventures. Next day saw me at the Model Duke well and hearty, and Ramasami saying "Na, No, Na, No," and "Taisnana." I found all the plants in good order with the exception of tea, and in the sacks the plants got heated and a good few have not rallied.

The big bushes were a great success and the plants in splendid order. I lost no time in planting out, and my success I have formerly described to you. My second trip in August was with more success and fewer adventures as the weather was milder and rivers shallow.

The Government made me a road to the door of my house, a good carriage drive. Mr. Palmer was the first to drive up to my bungalow. One morning I got a surprize. The Commissioner of Monlmein, Col. Plant, and the Deputy Commissioner of Tavoy, Mr. Duke, drove up in their carriage and pair; also Mr. Palmer, Deputy Conservator of Forests, and friend. Mr. and Mrs. Bailey often ride or drive up to see me. Mrs. Bailey is a capital horse-woman and fears neither rain nor sun, goes tearing on at the gallop sometimes. Dr. and Mrs. Dawson also drive over to see me. Dr. Dawson is my standing friend for my coolies: a good few got fever after we returned from Nat-ya-doung, and I only lost one cooly, poor fellow. I had him cured before I went to Nat-ya-doung and left him well and working, but on my return I found him too far exhausted, and had him removed to the hospital in Tavoy where he died. Had I been at home I would have saved his life. He was a nice boy and I was sorry to lose him.

But, Mr. Editor, I must not forget to inform you that I have gained the "bonus" from Government, and have been paid by "Rajah Bernard," and I now can claim being the first practical planter "pioneer planter" in British Burma, three-and-a-half times as large as Ceylon.

The Government are now pressing on the "Siam Road" the pack of men to be sent here, Engineers Sage, Smart, Wallace, Cox, Mathews, Sager, McLeod, Rose and other sixteen men I don't know. Coolies are coming down by the 1,000; elephants, mules, and a strong transport for supplies. Bailey is at the head Executive Engineer, etc., and the work is to be pushed on for 36 miles *cart-road* 16½ feet (80 miles bridle-road 6½ feet). One man is coming that was with Lord Wolseley who gained decorations of distinction in Egypt, in Telegraph Department. I shall not be so long in writing you next time, and will give some experience of ginger, tobacco, jute, etc.

Glad to see you have returned from England and Scotland. I greedily read all your letters with interest.

THE CULTIVATION AND PREPARATION OF RHEA FIBRE.

It is time that Ceylon planters were looking to their laurels as the pioneers of "new products"; for, notwithstanding that attention was first called by a Ceylon planter (Mr. Kay-Shuttleworth) in our columns to the field presented here for the systematic cultivation of rhea, planters in Southern India are likely to lead the way. Perhaps, in this matter of fibres, Ceylon planters may be quite content to await the results of the pioneering work to which we are about to refer, in Wynaad. But our own hope was, and is, that capital for an experimental Fibre Plantation in Ceylon would be forthcoming from that wealthy manufacturing town in the old country, "the Jute Capital," to which a new fibre or a liberal supply of one of proved excellence means so much. A Dundee-Ceylon Fibre Plantation Limited Company with a capital so modest as even from R50,000 to R100,000 ought to be able to test, on a regular plantation, not only rhea but several other indigenous or imported fibrous plants, and among so wealthy a body as the jute manufacturers of Dundee, there should be little difficulty in having the shares placed. We commend the idea to the gentlemen connected with the General Fibres Company Limited, and with Death & Ellwood's Machine, as well as to old Ceylon residents in Dundee and the neighbourhood. The report of progress in the cultivation of rhea and other fibres comes from the *Madras Mail*, where it is said of the operations of the Glenrock Company, Wynaad:—

Thirty acres of heavy forest land, forming the slopes of the hills surrounding the mill, so that there should be at little carriage of the green stems as possible, have been selected for the cultivation of the rhea nettle, now numbering 200,000 plants, in thriving condition, the result by successful propagation from the original stock of 2,400 rooted seedlings obtained by the Company between January and May last. The large forest trees in the clearing have been allowed to stand, to afford shade and protection; while the smaller trees and undergrowth were rooted out, and the ground well dug over. The drains are at distances of six feet apart across the slope of the hill, and serve a three-fold purpose: firstly, as catch drains, to intercept the wash which, in a heavy shower, is considerable, and greater in proportion to the steepness of the slope; secondly, as irrigation channels in which the water can be held, while saturation of the soil proceeds; and thirdly, as paths found to be necessary owing to the thick growth of the rhea, and the difficulty of otherwise moving about the plantation. At first the plants were put out at distances of 18 inches apart, but it was soon found necessary, owing to the vigorous habit of the plant, and the forcing character of the soil, to remove the intermediate ones, and all extensions are now put out at three feet apart. During the heavy monsoon rains, it was difficult to clear the under-growth and roots, which would not dry, and could not be burnt off, but the object being to save the season, and make the most of the few remaining months of the year during which planting operations could be successfully conducted, some expenditure was incurred in carrying the jungle stuff off the field. The established rhea in three months throws out vigorous shoots from the collar, which, when about six inches high, are removed from the parent plant, with their roots, and have been found the best. The greatest success has attended this method of stocking the plantation, though cuttings put down in nursery beds readily take root, and subsequently admit of transplanting without any very large percentage of failures.

Although rhea is the principal staple on the Glenrock estate—other fibre plants, on a less extensive scale, are being cultivated on land not suited for rhea, such as the aloe, the *Fourcroya*, the New Zealand flax, and *Colotropis*. Sufficient progress with these has not yet been made to enable an opinion to be pronounced regarding the suitability of the climate, and the locality; but the subject is borne in mind by the energetic and enthusiastic Superintendent of the Company, Mr. J. W. Minchin, who is carefully noting all matters of interest to the new industry. The fibre now being treated, is the young stems of the indigenous *Marocarpus*, of which there are several varieties in the forest. It is naturally a weakly plant, loving shade and moisture, but when cut down or layered along the ground, it throws out numbers of young shoots

which in from two to three months are from three to four feet long. Divested of their foliage, these stems are passed through Death and Ellwood's machines (Smith's patent) in handfuls of five or six at a time, the smaller, delicate end being first inserted, and cleaned nearly to the thicker end where held in the hand, when the wisp is slowly withdrawn, and the unfinished end passed into the machine for the completion of the operation. The fibre, when wet, is white, clean, and soft, but as it dries the gum asserts itself and the fibre gets stiffer; in this state appearing like the China grass of commerce, as hand prepared by the Chinese, and worth from £45 to £50 per ton in England. Samples of this same fibre chemically treated, from which all the gum was extracted, are beautifully white, and as soft and pliable as silk. In working the machines,—of which there are eight—three expert men are required, who change places among themselves: one on the right of the machine—and one on the left, to feed the green stems, while the third man supplies the other two with handsful of the stems as required from the heaps weighed and stored before the machine. Behind a boy receives the wisp of fibre as it is drawn from the machine, and after wiping it down with a cloth to remove the moisture and gummy matter, hangs it on a bamboo rod provided for the purpose beside him. As the rods are covered with fibre, other boys remove and fix them in niches prepared for their reception in the drying shed, where they are left until dry.

The work at present performed with the machines is on a limited scale, and is intended to give the operatives experience and celerity in the manipulation. The greatest quantity of work yet done is rather less than the passing of 3 cwt. of young green stems of wild rhea per hour, instead of the 10 cwt. promised in the advertisements of the General Fibre Company. But as the men acquire experience the outturn may reasonably be expected to be much greater. The eight machines have been erected, and are driven by a powerful turbine formerly intended to drive the stamping gear of the Gold-mining Company, and in stead of the pump, which are supplied with the machines, being used to cause the jet of water by which the fibre is washed during treatment, the water is taken off from the bottom of the turbine columns, and by this means a much greater force is obtained. The drying shed is to be provided with steam pipes for beating the air, and is of capacity sufficient to dry off a single bale of fibre at a time. Owing to the humidity of the climate it has been found necessary to press and bale off the fibre immediately after it is dry, for which purpose a screw baling press is in process of erection. During the monsoon it is impossible, without artificial appliances, to dry the fibre. A boiler will supply the steam for heating the pipes in the drying shed, and at the same time will be found useful in the Favier decortication process for boiling the alkali lyes for preservation of color and prevention of mildew, as well as for the chemical mixtures in which the fibre is steeped in subsequent processes. The vast and miscellaneous stores of machinery on the premises, sent out for the goldmining operations, have been largely utilized, and the Europeau artisans on the spot, whose terms of service with the Glenrock Company have not yet expired, are turning their ingenuity to the best account and showing the greatest zeal in starting the new industry.

On Glenrock, therefore, special advantages are found, but not greater than are presented in many districts in Ceylon where water in abundance for power as well as for decorticating or bleaching purposes is available. We have now received the detailed report of the trial of the patent Rhea Machine in Calcutta, and we see that what was done in 23 minutes and "could be done by Madras natives in 9" was not work supposed to be done by hand as might be inferred, but with the machines —the natives referred to being the men who had gained experience of Death & Ellwood's machine in Madras. The full report in the Calcutta *Englishman* is as follows :—

FIBRE-EXTRACTING MACHINES.

Mr. Death has been rather unfortunate, not only in the unsettled state of the weather, which kept everyone who was not actually interested in fibres away from the public trial of his machine which took place on Saturday, but also in the absence of the assistance he calculated upon to render that trial more perfect, as he had engaged two trained Madrasees who have been working similar machines in that presidency to exhibit their skill, and the capacity of the machine in the hands of an ordinary native workman, but the steamer, in which they left Madras on the 18h inst. had not arrived up to the time of going to trial. Despite the rain and uninviting aspect of the day, about twenty-five people had collected in the shed by 1 o'clock, when Mr. Death, protected all over by a waterproof against the spray from the machine, began operations with 12 lb of fresh rhea stalks, cut that morning. Single-handed, using only one machine of the pair and feeding three stalks at a time, he completed the whole quantity in 23 minutes, and that with perfect ease, without the least attempt at hurry, in fact talking a good deal all the time. The Madrasees would have done the same quantity in 9 minutes working the pair of machines. The engine is a vertical portable of 4 H-P. with 50 lb of steam, and working 600 revolutions a minute. It is quite capable of working another pair of machines at the same time and at the same speed. Each machine can strip 3,500 stalks per hour, or in a working day of 10 hours one engine and its four machines can strip 140,000 stalks, or 46,500 strings of rhea per day, requiring four trained workmen and four cooly attendants merely to hand the stocks, which are held lightly in the hand and allowed to be drawn in by the breakers. When half the stalk has been treated the hand is lowered, and the fibre tightened on the feedsplate and drawn quickly, but evenly back, when the stalks are reversed and the other half treated in the same way, which is also drawn out by the same motion. The string, as it is now called, is then hung up to dry. Every "eye" along the stalk, that is, every place where a leaf has been, will occasion a certain amount of breakage in the fibre. All such broken portions are collected together at the end of the stalk, and are subsequently cut off. These tufts are to rhea what "Chunsen" is to silk, only of relatively greater value, as 'rhea waste,' as it is called, brings within £8 per ton of the average price paid for the baled fibre, and is made into the best Whitney blankets. The fibre requires no further process whatever. When dry it is tied in bundles about 9 to 10 inches in circumference, doubled across the centre and baled. It still retains a small portion of gum which is latent in the fibre and exudes in the process of drying, but this, so far from being any harm, is a decided advantage, as it protects the fibre from damage during baling and subsequent shipment and carriage, and is easily removed by the manufacturer before being worked into its intended fabrics. The machine itself is beautifully simple, consisting of a hollow cast-iron cylinder or drum 18inches diameter and 14 inches wide, with brass angle bars projecting about one-inch-and-a-half from the outer rim. These are the breakers. In front is a flat feed-bed made of heavy white metal with flanged sides and adjusting screw to regulate the distance between it and the breakers, so as to suit anything from plantain to sunn. There is a movable sheet iron cover over the drum, and all the parts of the machine are very neatly finished. Beneath the feed-bed is its speciality—a perforated pipe which throws a very powerful flattened jet of water against the fibre. It is sufficiently strong to remove and carry away every portion off the woody centre of the stalks after it has been broken up by the breakers, and aided by the high rate of speed it keeps the string curved round the drum which scrapes on the bark, and washes out the gum and fecula in the stalk and turns out the fibre ready for baling. The Death and Ellwood is no doubt a perfect success, in so much that it does all it professes to do, and it does it expeditiously, cheaply and well. In the warm weather of April and May living rhea could be cut in the morning, passed through the machine, dried, tied, baled and shipped before sunset. This is due to the absence of any retting process, which is so dilatory, troublesome, and requires localities specially suited in the matter of steeping places. Rhea fibre is at present not much quoted in the home markets, because the supply is so uncertain that manufacturers do not use it. In 1870 it was selling in London at £120 per ton, but this is far above its value. At present it is quoted at £35, which again is far below the value. Once it becomes an established

industry with regular shipments, it should command from £60 to £70 per ton. An idea of its great strength and value in some instances may be gained from its use in hydraulic machines. Where hoses made of the strongest known vegetable fibre, not rhea, will only stand a pressure of 300 lb. rhea will stand 800 lb. and burst the machine, and has done so. Only rhea was tried on Saturday, but there will be another trial on Wednesday next after tiffin or at 3 p.m., when rhea and other fibres will be tried, as it is hoped the Madrasees will have arrived before then.

We shall watch with much interest the further prosecution of the Glenrock experiment, but the results will probably not be fully given to the public, more especially if the directors find they have "struck gold" at last, through cultivating rhea and other fibres. Let Dundee come to the front and establish a Plantation in Ceylon, on which every fibrous plant under the sun, if need be, can be tried.

COFFEE PRODUCTION.

[With the qualification that no very large decrease in coffee production has *as yet* taken place in Brazil, the following article is worthy of careful consideration, showing as it does that in a considerable proportion of the coffee growing countries of the world, production is diminishing.—ED.]

A majority of the coffee dealers of the country will say, if applied to for information on the subject, that the comparatively low price of the staple which has ruled in the principal markets during the past three years, is due to overproduction in consequence of the annual increase of the acreage of the plantations.

A careful sifting of the statistics connected with this important industry will not bear out the assertions of the coffee dealers, but will elicit the fact that for the last two years the acreage of coffee planting, in many localities, has sensibly declined, while the inquirer will discover that the number of coffee-producing plantations three years ago was sufficient not only to supply the demand at that time, but the call for coffee for several years to come. The following interesting details connected with coffee production in Central America, show that Guatemala is the only locality in that territory where coffee planting is on the increase, while Nicaragua, San Salvador and Costa Rica indicate a sensible decline. The production in Mexico also shews a decrease :—

Between Dec. 3rd 1883, and March 15th, the vessels of the Pacific Mail Steamship Company brought 177,896 sacks of coffee into Panama Bay. Of this number 5,230 came from Mexico, 90,059 from Guatemala, 29,534 from Salvador, 14 from Honduras, 2,387 from Nicaragua and 50,672 from Costa Rica. Thus Guatemala stands at the head of the list with more than 50 per cent of the total shipments, Costa Rica being second with a little less than a third of the whole.

The ports of the different republics from which the coffee came, and the amounts received in each, are shown in the following list :

Mexico.—Port Angel, 3,042 ; Salinas Cruz, 150 ; San Benito, 2,032. Total, 5,230 sacks.

Guatemala.—Tecojate, 4 998 ; Champerico, 67,414 ; San José 23,647. Total, 90,059 sacks.

Salvador.—Acajutla, 22,914 ; La Libertad, 5,890 : La Union, 741. Total, 29,534 sacks.

Honduras.—Amapala, 14 sacks.

Nicaragua.—Corinto, 2,252 ; San Juan de Sur, 135. Total, 2,387 sacks.

Costa Rica.—Puntarenas. 50,672 sacks.

The largest shipment, 61,414 sacks, was made from Champerico, and the smallest, 14 sacks, from Ampala the only port of Honduras on the Pacific coast.

In Ceylon and Java, while there are many fair sized plantations, the coffee industry is greatly divided up, and numerous small producers supply the demand. In Columbia and Venezuela and in Nicaragua and Costa Rica, the proximity of that great enterprise, the Panamá Canal construction work, and the high rate of wages that obtain on the Isthmus, have very materially affected the labor market in the above-mentioned countries, and thousands of the working class emigrate annually to that more fortunate locality. Thus the price of laber has increased the cost of production. In parts of Costa Rica this problem has assumed such proportions that many coffee plantations have actually been abandoned. We base our assertion up the late report of the Minister of Fomento of Costa Rica.

At Cordoba, Mexico, an analogous condition of affairs rules. Railroad enterprises give higher rates of wages. The agricultural laborers have deserted the plantations and have flocked to the railroads in hopes of obtaining greater compensation for their labor. In consequence the increased cost of coffee production has effectually prevented the increase of the acreage of planting.

Cuba, which, years ago, exported quantities of the precious staple, no longer produces a sufficiency for home consumption. In Santo Domingo and Puerto Rico no sensible increase of the acreage of coffee production has been visible for the past five years, while Jamaica scarcely considers this industry worthy further attention. In Brazil the labour supply question, in consequence of the abolition movement, has assumed alarming uncertainty. In that country, therefore, the acreage of coffee production has by no means augmented, while grave fears are entertained that the industry is positively on the decline. From the above, then, it will be seen that while at Colima (Mexico), in Guatemala, in Honduras, and perhaps in Java and Ceylon, the acreage of coffee planting is slightly on the increase ; * at Cordoba, Mexico, and in the other countries abovementioned, this industry is, to say the least, at a standstill, while in many of the localities it has actually declined. It is safe, therefore, to assume that the present coffee production will fill the demand for some time yet. But the increased consumption will eventually make an impression on the market, and coffee producers, who are now suffering from low prices, will then reap the reward of their courage and constancy.—*Rio News.*

CINCHONA PLANTING AND PROSPECTING IN GUATEMALA.

(*Extracts from an ex-Ceylon Planter's letters.*)

April 10th.—I received your long and to me very welcome letter, but, before replying thereto, I must give you a short sketch of my further wanderings since my return here (city of Guatemala). Almost immediately after my arrival from Ceylon with the cinchona seed, I started for the Mexican boundary, or rather "Porvenir," the estate of the President, which is situated near the boundary where I sowed my first seed ; thence I proceeded to the different coffee districts situated along the Pacific slope, at most of which places I sowed seed. I was 43 days in the saddle altogether before I returned to the city. The ride, of course, I did not mind so much, but the fare is of the humblest description as also is the accommodation. I had hardly been here a few days then I was off again to the opposite side of the Republic, the Department of Coban on the Atlantic Coast. Here I formed seven other nurseries, and then returned again to the city. I have been here about three weeks, and leave again in a few days on a visit of inspection up the Coast.

This is Holy Week and no carriages, horses, or other vehicles are allowed in the streets, and, if one is so bold as to go outside the city, the first pueblo or village he comes to, he would be sure to be stoned. As I don't wish to die the death of a martyr just yet, I prefer to keep my hotel until all this 'cussed" foolishness is over. I am pleased to say that *all* my nurseries have sprouted, and in a short time, two or three weeks, "pricking out" shall be begun. How weary and tired of this continual wandering I am, I shall leave you to imagine: my very soul calls out for rest sometimes, and still this constant change has inspired me with a feeling of restlessness, so that even a week or two of the city makes me long again for the saddle and the road. I paid Mr. A. 100 dollars a month all the time I was away in Ceylon, for preparing the nurseries.

August 8th.—I write you now on the shores of Izabal, at a small town of that name on the Atlantic Coast: if you have a map to refer to, the lake may be marked the "Gulf of Dulce." My business along with that of all others has been greatly retarded by the Government's attention being wholly occupied in finding out the perpetrators of the crime of the "bomb," of which I told you in my former letter [not received.--ED.] This crime had more political significance than at first appeared; in fact, was a plot of great and widespread extent, to overthrow the present President Barrios and his Government, and many of the leading men in the country were mixed up in it. You cannot imagine how rejoiced I and all the foreigners were, that the whole thing failed. He, General Barrios, is the only man the country has seen, who has tried to force it out of its priest-ridden state and make a country of it. I could relate to you many things which would greatly interest you, of the desire of this man to do something for these people and the good of the country; and the only return he has received, is to be plotted against secretly; and his life attempted—his escape from the bomb was almost miraculous. I am touching on all this again as you said you did not receive all the letters I wrote you. This plot put all business at a complete standstill; and the natives were almost always shut up in their houses afraid to stir out, and there was simply nothing to be done with the Government. The general belief at first was that some fool who had a spite against or dislike to the President had attempted his life, but on my return to the city, instead of things being quieted down, they were worse than when I left. I was very much vexed and put out of sorts, as you can imagine. I had scarcely returned to the city a few days when I met the contractor for the railway from the Porte San José to Guatemala. Mr. N. asked me to go and select for him and his firm a block of land which was in their concession or contract, about 190 000 acres; this, of course, was rather a difficult piece of business to do, as the greatest portion and the best of the land is taken up. However, I consented, and left for the Atlantic Coast about the middle of June, and since that time I have been buried in the jungle, far away from all communication. I will give you a short outline of my journey so far, and you will have an idea of what a hard time I have had. I left Guatemala for Salama, two days' ride; thence to Coban by way of Purala. two days more. I stayed there to engage Indians and an Indian interpreter to take my baggage through the jungle. Very few of the Indians here speak Spanish. From Coban I rode to Cajabon, three days; sent mules back to Coban and entered the jungle on foot From there I went down towards the coast, struck the sources of the Sarstoon river, went earn to the boundary of British Honduras or Belize; then bore away south by east to the lake Izabal: this track has never been travelled before by anyone, except a man called Bailey. I crossed the lake in a canoe and went to the banks of the Matagira River; this river is about six times the size of the Thames. I went down the river bank 40 miles; crossed and walked to the boundary of the Republic of Houduras, and returned again two days ago. I hurried back as fast as possible to catch the river and lake steamer to take me up the Polochie River to Ranzos. I arrived here only a few hours after the steamer had left; so have to wait until she returns and goes to Livingston and comes up again, as there is only one steamer. I could ride round by way of Zacapa and Salama to Ranzos, but would not gain much time, as it would take me seven or eight days. I prefer to rest myself and mules and go by steamer. I have had an extremely rough time of it indeed. The rains are on here now, and from the time I left Cajabon till I reached the lake it rained nearly every afternoon, and in the morning a heavy fog hung on the jungle which condensed, and at the slightest agitation by wind, the water was precipitated on to the path and myself, which was not pleasant. I averaged from eight to ten hours walking between each camp. There were no houses or settlements whatever, except one Indian village in the heart of the jungle, called Chakah, where I stayed three days to recruit and get my shirts washed. After leaving Chakah, for three days' running we saw *tigers* which had been prowling round our camp all night—one I was within 20 paces of. Pigs, peccarries, tapir and turkeys *galore*. How the spirits of the mighty A. H. M. M. of Maturata and G. W. of Dikoya would have rejoiced to have been here! I return to Guatemala by way of Ranzos, and visit the Seiras del Minas mountains on my way back which will take some little time. I hope to be in the city again about September 18th. Some people I think are born like the "Wandering Jew" to travel for ever: guess I am one of them. I had one or two narrow escapes, but the deil aye taks care o' his ain bairns, and I am safe and well. This is a grand country, and you in Ceylon do not know what soil is compared with the soil one finds here. Remember me to all my friends. I shall write you again as to the progress made by my cinchona.—Yours, N. I. F.

ADVICE TO YOUNG CACAO PLANTERS.

(*By a Practical Man.*)

CACAO-GROWING IN PANWILA.

(*Continued from page* 386.)

It is of the greatest importance the pods should be well ripe and no light beans should be planted, as the seed from a half-ripe pod or imperfect seed will never give a plant which would grow up into a healthy tree. About two weeks ago I met the renter of Matale at the Mahayyawa station; he showed me four cacao pods he had purchased that day from the Peradeniya Gardens for one rupee—each pod was of a different kind. I had no difficulty in at once pronouncing them not ripe enough for planting.

The distance best suited to plant in nursery is from five to six inches apart; this will give you the most plants that can be grown; it will be easy to take them up without injury to adjoining plants; you will get sufficient soil with the plant, if carefully taken up, and there will be no stoppage in growth after planting out. The coolies, when taking out large plants with Scowen's transplanter, have a way in taking hold of the plant when pulling up the transplanter, and so either injure the stem of the plant or loosen the roots in the soil; though a European may do this successfully, coolies should not be allowed to do this; for taking out large plants get Holloway's fifteen inch deep by five wide transplanter obtainable at Scowen's or Walker's, and some tins to lay the plant on for carrying to wherever required on wooden trays holding six to eight plants each. The holes having all been carefully filled, you put on a cooly to make a hole by hand in centre of newly-filled hole large enough to allow you to put in the plant with soil as taken up by

transplanter. The plant having been put in hole, be careful the cooly fills in soil all round the plant and presses this soil down, but on no account should he be allowed to touch the soil taken up and put in with the plant. It is always well, especially during the changeable weather, to shade plants: some use cadjan hoods; others, ferns or cuttings from mora or other trees. Next you have to contend with white-ants, white grub, jungle rats and porcupines: you will find wood-ash, lime and the powdered shells of croton-oil husks a check on ants and grub; rats and porcupine, you must catch either by traps or poison. You should supply vacancies every three months. The thicker the shade the more rapid is the growth of plant above ground: some planters like the plants to fork out low; some prefer to see them grow high before forking out: if thin shade, the plant will not grow fast upwards but makes good roots first, then it will grow up all right.

The cost of planting cacao estate has been given by Mr. Jardine and the curing by Mr. Tucker in the *Tropical Agriculturist* so fully, that I will not take up those subjects again. Water trenches, bulky manure, wood-ash and lime dusting are useful. The scare about *helopeltis*, fly and borer I treat with contempt, as these can be kept well checked—what produce has not its enemy? Our cacao in this valley is bearing very heavily, and trees are in good heart.

J. HOLLOWAY.

ALTERED CONDITIONS IN THE TEA MARKET.—A RETROSPECT.

[The following article from the *Home and Colonial Mail* is well worthy the attention of tea planters in Ceylon as well as India. Lowered prices, in view of keen competition, are inevitable, but can be compensated for by economy in production and increased demand.—ED.]

There is scarcely any fact connected with the history of the Indian tea industry more remarkable than the manner in which those interested in it have accommodated themselves to the necessities of the position. We refer especially to the depreciations in the value of the article, and to the consequent demand for increased economy in the cost of production. Without looking back so far as 1862 when, to take the case of the Assam Company, an average of nearly half-a-crown a pound was obtained for a crop of over a million lb. of tea, or even to 1875 when that company's crop of 1¾ millions lb., realized over two shillings a lb., and cost a proportionate high rate to produce, we may refer to a period but five years ago, from which to point the moral which we wish to lay before our readers. In 1879 before the lesson of economy had been thoroughly learnt by all those concerned we find that few gardens in Assam were working profitably, and taking again the leading company as an instance we note that although its crop realized 1s. 5½d. per lb., the cost of its production was as high as 1s. 4d., leaving a margin of only 1½d. per lb. as profit. It is true the company hoped to be able to lay down the following year's crop at 1s 3d. per lb., but scarcely any one looked in the right direction viz., reduced cost of working, as a remedy for the evil of a low market. Meanwhile the Borelli Company showed even in 1879 that tea could be laid down in London at a cost of 11⅞d. per lb. and we now see that the old Assam Company in spite of the conservative character of that institution contrived to put its crop of last season into the market at the comparatively low cost of 11½d. per lb. In the meantime we find that a well managed concern like the Borelli Company has been able to reduce its cost of working from 11⅞d. per lb. in 1879 to 10½d. per lb. in 1883, thus producing a profit by adapting its expenditure to the necessities of the position. Nor is it alone in this enviable condition. The Brahmapootra Company has also solved the difficulty, and lays its teas down at 10½d per lb. Two concerns whose working is shown in the valuable table of statistics published by us have proved that it is possible to put their crop of tea in the London market at a rate which if it had been spoken of a few years ago among planters would have been pronounced impossible. But facts are stubborn things, and we may point to the Tiphook Company producing 345 lb. of tea per acre at a cost, inclusive of all charges, of 9½d per lb. as a model Assam concern, while the Chargola Company, making the same quantity of tea per acre at the low rate of 9d per lb., is an instance of what a Sylhet garden can do. Viewing these facts in the right light we may well bid planters be of good courage, even though the price of tea is destined to fall somewhat lower than we have yet seen it.

JAMAICA AT THE NEW ORLEANS EXHIBITION 1884-85.

There is an intimate relation and increasing trade between the West Indies and the United States, and it is no wonder that Jamaica, Trinidad and British Guiana are making an effort to be represented at "the World's Exposition at New Orleans." For Jamaica Mr. D. Morris (ever to the front) has drawn up a catalogue of articles illustrating the agricultural and industrial products of the island, including premium list for fresh tropical fruits: intended as a guide for the use of persons preparing exhibits. This was compiled at the request of the Governors of the Institute of Jamaica, and Mr. Morris, whose official title is Director of Public Gardens and Plantations, is good enough to send us a copy. Of the Exhibition we read:—

The exhibition promises to surpass in size and number of exhibits that of the London Great Exhibition of 1862, as well as the recent Centennial Exhibition The London buildings of 1862, which up to that time was the largest exposition structure ever erected, contained 1,400,000 square feet. But the main building at New Orleans will contain 1,656,000 square feet. The centre of the hall will be devoted to an international fruit display, presenting 20,000 varieties. This is nearly double the quantity of any previous fruit exhibit.

Further:—

New Orleans, as the great metropolis of the Southern States of America, is admirably connected by River and Railway communications with all the chief centres of industries to the West and North. New Orleans has been happily termed the "gate-way" of the United States to and from Mexico, Central America and the West India Islands. And the immense resources and commercial interests of these countries are being greatly expanded under the influence of the increased facilities and ready markets of recent years offered for their produce. To the British West India Islands, and especially to Jamaica, this World's Exposition at New Orleans affords the means of placing their rich and varied tropical productions in all their freshness and luxuriance before the world; and they should be among the first to supply the tropical fruits and raw tropical produce which are in keen demand by a population numbering over fifty million souls. With a large and well-appointed Jamaica Court, and with a judicious and generous display of our tropical productions, there might be created a permanent impression of her capabilities amongst the prosperous communities of the Great Republic. This would naturally serve to develop trade and bring this Island and the Southern States into much closer communication than exists at present. During the last ten years the export trade of Jamaica with the United States has nearly trebled; in 1874 it was £122,041, while in 1883 it was £310,274. The chief increase in this item has been in the exportation of fresh fruit which in 1874 was only of the value of £10,208. In 1883 this had reached the total value of £153,108, shipped principally, if not exclusively, to the Northern ports of New York, Philadelphia and Baltimore. The great demands of New Orleans, which supplies all tropical produce to the Central and Western States have hitherto been exclusively supplied by the Central American States and Mexico; but there is no reason why Jamaica should not supply a large proportion of the best class of tropical fruits and so increase her exports under this head to an aggregate of half a million sterling annually.

The Catalogue of articles, which may be exhibited from Jamaica under groups "Agriculture," "Raw and Unmanufactured Products" and "Alimentary Products," is of interest. Thus for coffee:—

Class III.—Coffee—(*C. arabica, C. liberica*).—Being the next staple commodity after Sugar and Rum, samples of Coffee are invited to represent all grades. Sam-

ples consisting of not less than 3 pounds by weight, should be packed in hermetically sealed clear bottles, and marked with the name of estate, brand &c. 1. Best Blue Mountain Coffee; 2. Best Native grown Coffee; 3. Best Settler's Coffee; 4. Liberian Coffee; 5. Mocha Coffee.

Class IV.—Pimento—(*Pimenta vulgaris*).—In this important and almost essentially Jamaica product, there is not much scope for competition. Samples may, however, be forwarded of good qualities shewing the results of the best system of curing. The exhibits should be in glass bottles containing not less than 2 pounds. 1. Best cured estate Pimento; 2. Best cured Settler's Pimento; 3. Samples of dried Pimento leaves; 4. Samples of Pimento oil obtained by distillation from the leaves; 5. Pimento cordial.

Class V.—Cacao—(*Theobroma Cacao*).—Cacao cultivation being largely extended, this article should be represented in any collection of Island products. Under this head might be shown samples of cacao (chocolate) fermented and unfermented; clayed and unclayed, &c., as under.—1. Best plantation Cacao—fermented and clayed; 2. Best plantation Cacao—fermented but not clayed; 3. Best Settler's Cacao; 4. Best manufactured Chocolate Cakes or Prepared Cacao.

Class VI.—Ginger—(*Zingiber officinalis*).—Jamaica Ginger being the finest in the world, should be well represented in all its stages. 1. Jamaica Ginger, unscraped; 2. Jamaica Ginger, scraped and cleaned: 3. Preserved Ginger; 4. Essence of Ginger; 5. Ginger Cordial.

Class X.—Cinchona Bark.—Among the new products for which the Island is becoming known, Cinchona Bark of good qualities is an important element. These for the most part will doubtless be contributed by Government. Contributions from private planters are also invited. 1. Crown Bark (*Cinchona officinalis*); 2. Red Bark (*Cinchona succirubra*); 3. Yellow Bark (*Cinchona calisaya*); 4. Hybrid Bark (*Cinchona Hybrid*); 5. Ledgeriana Bark (*Cinchona ledgeriana*).

Class XII.—Oils.—These oils may not be producible on a commercial scale at once; but if a large demand arose for any of them, they would be capable of being produced within a short time. Samples of the following obtained by pressure without heat are desired:—1. Cocoanut oil (*Cocos nucifera*); 2. Cashew nut oil (*Anacardium occidentale*); 3. Oil of Ben (*Moringa pterygosperma*); 4. Gingelly or Wanglo oil (*Sesamum indicum*); 5. Ground Nut or Pindar (*Archis hypogea*); 6. Santa Maria nut oil (*Calophyllum calaba*); 7. Sano box seed oil (*Hura crepitans*); 8. Autidote cacoon oil (*Feriltea cordifolia*); 9. Candleberry or Walnut oil (*Aleurites triloba*); 10. Castor Oil (*Ricinus communis*); 12. Avocado Pear Oil (*Persea gratissima*); 13. Maccafat oil (*Elaïs guneensis*.)

FORESTRY EXHIBITION.—May I point out that in one of your interesting articles on this exhibition, at p. 298, in the issue for September 6, the beautiful wood known as Andaman Marble-wood is not furnished by Diospyros quæsita, as there stated, but by D. Kurzii, Hiern. Gamble, in his *Manual of Indian Timbers*, describes the tree as an evergreen, with very thin, smooth grey bark, and handsome wood, streaked with black and grey. It is used for cabinet work, and should be better known as a substitute for the Ceylon Calamander wood, which it much resembles. In the Andamans it is used for handles and sheaths of blades, as well as for furniture. The tree grows in the Andaman Islands and Nicobars. These facts I have pointed out in the new guide to the Kew Museum. Diospyros quesita, Thw.. is the true Calamander, or Coromander wood, and is a large tree of Ceylon, now scarce, though the wood is in great demand for ornamental articles and inlaying. —JOHN R. JACKSON, Museum, Kew.—*Gardeners' Chronicle.*

FERTILITY OF HYBRIDS.—Apples, Pears, and Cherries when two or three years old, will often flower freely, but produce no fruit. The same trees, the year following transplanting, are well known to attempt to mature of heavy crop in many cases. The checking of vegetative, vigour is favourable to reproduction. It is not a structural case having relation to pollination. In the history at American fruits we find remarkably strong evidence for the fertility of hybrids. The old "purple-cane" Raspberry is either a natural hybrid, or a departure by natural variation from some native species. The "Philadelphia" Raspberry appears to have this for one of its parents, and is also either a hybrid or great variation. Found wild, there is no evidence of a positive nature. They are simply supposed to be hybrids between the Blackcap Raspberry, Rubus occilentalis, and the red, Rubus strigosus, or Rubus Idæus. However, with this "Philadelphia" and Rubus occidentalis, Mr. William Saunders, of London, Ontario, has numerous fertile hybrids. (See *Fruit Growers' Ontario Report*, 1872.) In 1875 he also had fertile hybrids between Rubus occidentalis and some "red" Raspberry. The same remarkably careful scientific experimenter had fertile hybrid Gooseberries between Ribes Cynobasti and the garden Gooseberry. The history of the Grape in America is one of a long succession of fertile hybrids, though perhaps the distinctness of the species might be a question. There is such a regular gradation, that no one can refer a form in every case to its proper species. Still, when we take the wild Fox Grape and compare it with the Grape of European vineyards, or a Scuppernong and a Frost Grape, all will admit that in no sense can these be regarded as one species. Yet they all hybridise, and the hybrids are fertile. Dr. Wylie, of Chester, South Carolina, succeeded in uniting Scuppernong and Black Hamburgh. There are always some males or sterile plants among all Grape seedlings, hybrids or not. M. Naudin, a very energetic French experimenter with hybrid plants, gives as the result of his observations, that never more than 25 per cent of hybrids were sterile, and of these numbers had fertile pollen; but even this proportion may have had more to do with the climate or surroundings than with absolute sterility, In America, so far as the writer of this has had the opportunity to observe, there is no reason to believe there is any more sterility attached to hybrids than to ordinary plants.—THOS. MEEHAN.—*Gardeners' Chronicle.*

NEW PRODUCTS IN BORNEO.—Says the *North Borneo Herald* of Sept. 1st:—"In the *Gazette* of this date are published some special regulations for the sale of land for the cultivation of gambier and pepper. A brother-in-law of Mr. Tang Keng Swee of Singapore, who has a very large interest in the Johore gambier and pepper plantations, is visiting Sandakan with the view of selecting land for this culture. The benefit which has accrued to Sarawak from the advent of Chinese gambier and pepper planters was referred to in the leading article of our last issue, and we sincerely trust that we may shortly have the pleasure of chronicling the fact of the opening of gambier and pepper plantations in North Borneo." The main provisions of the regulations are as follows:—

"Should the application be accepted the land selected will be roughly defined, and a permit under the hand of the Governor will be given to the applicant to occupy such land, rent free, for three years from the date of such permit, but subject to the following conditions:—Such permit will specify the extent, and describe generally the situation of the land to which it relates. At the end of such three years a rough survey of the land so occupied will be made, the permit will be called in and cancelled, and a regular lease for 99 years will be granted in lieu thereof, for so much of the land so occupied as shall then be actually under cultivation, and for so much of the uncultivated and uncleared part of such land so occupied as shall be equal in area to two-thirds of the land then under cultivation, the whole being subject to the payment of an annual quit-rent of 10 cents per acre. The Lessee shall pay such sum for the expenses of survey, demarkation of boundaries, transfer or registration fees, or expenses of conveyance as the Governor shall fix, which shall not exceed one-half of the expenses and fees payable under any then existing Land Regulations approved by the Court of Directors. Landmarks will, in the first instant, be set up by the Company, but will be kept in repair at the expense of the Lessees. The Company reserves the right to impose an export duty on gambier, pepper and all other produce of such lands, but such duty shall not exceed 10 cents per picul on gambier, and 20 cents per picul on pepper during the period of ten years, computed from the date of these Regulations."

MR. LAWSON'S FIRST REPORT ON THE NILGIRI CINCHONA PLANTATIONS.

This formidable-looking document, with no fewer than seventeen figured statements attached to it, was sent in to the Madras Government in July, so punctually to time that Government specially complimented the Director on that account. The year 1882 was a year of excessive rainfall in Ceylon as well as in Southern India, but we do not suppose that anywhere in Ceylon did anything like so much as 102 inches fall in one month, as was the case at Naduvatam plantation in July 1882. The reaction in the following season was so great that only 102 inches (exactly the fall in July 1882) was recorded for the twelve months. The comparison was (the official year running from April to March):—

102 inches spread over 162 wet days as against 178 wet days in 1882-83, when there was a fall of 195 inches of rain. The maximum fall was in July, when 32½ inches fell as against 102 inches in the same month of the previous year.

The rainfall at *Dodabetta* was 51·49 inches distributed over 140 days as against 61·35 inches in the previous year. The maximum fall occurred in October, when 12·63 inches of rain fell. In January only one inch was registered, while during the two months of February and March there was no rain at all.

It will thus be seen that the rainfall at Dodabetta (the highest mountain in India south of the Himalayas) is only about half the average at Naduvatam, some twenty miles distant. The latter estate, although 1,000 feet lower in elevation (6,000 feet against 7,000), is more in the track of the south-west monsoon. The comparative rainfall on the other two estates under Mr. Lawson's charge is thus noticed :—

Hooker.—The amount of rain registered was 92 inches as against 143 inches in the previous year. The greater fall occurred during July of both years, but the rain which fell in July 1882-83 was just double (62 inches) of the amount which fell in the corresponding month of 1883-84.

Wood.—Here the rainfall amounted to 93 inches as against 155 inches in the previous year; the maximum fall, as in the above two estates, occurred in July, 28 inches being registered as against 71 inches in the previous year.

The great difference between the climate of Ceylon and that of Southern India (we may add India generally) is the more equable distribution of rain fall over the year in our island. Practically all but a trifling proportion of the large rainfall of 18 2 (195 inches) at Naduvatam fell in the five months between June and October, thus :—

June	..	34·70 inches.
July	...	102·11 ,,
August	...	16·94 ,,
Sept.	...	12·61 ,,
Oct.	...	12·20 ,,
Total	...	178·56 inches.

In 1883-84 the bulk of the rainfall, 102 inches, was crowded into so few as three months, thus :—

June	...	15·13 inches.
July	...	32·48 ,,
August	...	27·76 ,,
Total	...	75·37 inches.

It is not climate, therefore, but rich, deep, free, soil which favours cinchona culture on the Nilgiris, and how terribly climate (not only rainstorms but frost and hail) counteracts the benefits of soil, we shall now see. Mr. Lawson reported :—

Season—Dodabetta.—The season on the whole was favorable both for the growth of the trees and for the carrying out the general work of the estate. Many, however, of the younger plantations, especially in exposed situations, were much injured, first by the severity of the frosts in the early part of the year, and secondly by the prolonged drought which followed. On one particular plot it is estimated that no less than 50 per cent of last year's plantings have been killed. There were also fifty beds of cinchona seedlings in the nursery on Plot VIII, which were entirely destroyed.

Naduvatam.—The season on this estate for nine months was exceedingly good for the growth and recuperation of those older plantations which had suffered so much from the storms and winds of the previous year, also for the growth of the younger plantations, and at the close of the year the greater part of the estate looked very promising, particularly the younger plants in Plots XVIII to XX and XXI, the growth of which has been most satisfactory.

Hooker.—This estate suffered very severely from a hail-storm that occurred in April and which killed almost all the *Cinchona succirubra* and injured very many *C. officinalis.* (Most of the former had to be uprooted.)

The drought at Naduvatam and Hooker, which lasted 107 days continuously, was very unusual, but comparatively not hurtful. The frost did a little damage at Naduvatam and much at Hooker. Private estates in and around Ootacamund were seriously injured, and many almost ruined. Whole plots of three and four years' growth were cut down to the collar and in some cases to the root.

Wood.—The drought on this estate also was very severe and retarded the growth of the young plantings. The frost also caused some injury to this estate.

All this is surely as bad as our "dying out" of cinchona plants in Ceylon, so that when the editor of the *South of India Observer* asks "How came the Ceylon planters to choose unsuitable soil?" it may well be retorted on him "How came the Nilgiri-planters to choose an unsuitable climate?" But the case is one for mutual sympathy, low prices following on disasters to cultivation. The bark from the Government plantations of the Madras Presidency, in previous years so much sought after at high prices, did not last season average more than the cost of production, or about 1s 1½d per lb. The cost in the British Sikkim (Darjiling) plantations is usually reckoned at 2 to 3 annas per lb., so that culture in Eastern India must be cheaper or there must be a different mode of keeping accounts. But we are anticipating. Mr. Lawson reported :—

Credit is taken in Statement 5 for the sum of R1,740 for 1,000 lb. of mossed red bark supplied to the Bombay Medical Department at R1-9-0 per pound, this being the average price realized at the Madras auction sales during 1882-83.

Rupees 55,896-10-5 were realized by the sale of 62,616 pounds of cinchona bark sold by public auction in Madras. These prices compare favorably with those at home, and, when consideration is made of the risk and trouble of shipment and of the many incidental charges attendant upon sending bark to England, there is no doubt but that the suggestion made in the latter portion of para .4 of the Right Honorable the Secretary of State's Despatch recorded in G. O., No. 623, dated 10th May 1884—to the effect that further sales of bark should be held *in this country*—will result in a material saving if carried out.

The proceeds realized by the sale of cinchona plants and seed amounted to R4,352 as against the budget estimate of R5,000; the difference is due to the fact that nearly all the older private planters have filled up their estates, and that the present low rates obtained for bark have deterred others from opening out new ones.

The expenditure was R94,181, and Mr. Lawson explained :—

It will be seen that the actual expenditure has been less than the estimated expenditure by R14,328, while the actual receipts have fallen short of what was estimated by R22,260. This deficiency is due to the heavy fall in the value of the bark which was sold at the last sales.

The figures for trees in the plantations show an enormous falling off from the number assumed by poor Mr. McIvor, who took no census and did not allow for deaths :—

Number of plants in permanent plantations on 31st

March 1883, 9,67,795. Number of trees uprooted, 23,672. Number of trees coppiced, 18,936. Number of plants planted out permanently, 3,90,259. Balance end of March 1884, 1,315,146.

There are a great number of private plantations in Ceylon which can, even now, number more plants than exist on the four original plantations on the Nilgiris. Mr. Lawson remarked on the figures:—

It will thus be seen that 1,315,146 trees existed on the Government cinchona estate on 31st March 1884 as against 967,795 in the previous year, but it must be recollected that quite half of this number, if not more, consist of young plants, which will take some years to come to maturity. The reason why so many more plants are to be found now than existed formerly upon the same extent of ground is that the trees are planted out 4 feet by 4 feet instead of 6 feet by 6 feet

Dodabetta.—The trees on a considerable portion of this plantation at the close of the year looked in fine condition, but on some of the older and more exposed sites there were so many signs of the trees having passed their prime that I have directed that they should be coppiced. The trees on Dodabetta are (*C. officinalis* about 22 or 23 years old, and they had been repeatedly stripped. Mr. Lawson went on to state:—

The *Cinchona carthagena* plants, which were put out last year, have made but little progress, and I do not think that this species will thrive at this high (7,000 feet) elevation.

The *Cinchona Santa Fé* was proving a complete failure when I put the single surviving plant into the hands of Mr. Jamieson, the Curator of the Government Gardens and Parks. Since that time the plant has steadily improved, and Mr. Jamieson has been able to raise from it seven healthy cuttings.

The seed of *Cinchona verde* and *morada*, which was bought last year from Mr. Christie, was also raised by Mr. Jamieson in the garden propagating houses, and, when ready will be planted out in the nurseries at the wood plantation.

To prevent damage from the tresspass of cattle, I have put a wood and wire fence round about three-fourths of the whole estate.

Nadavatam.—The trees on a large portion of this estate present, as at Dodabetta, a fine appearance, but as on that estate, so here, there are many plots on which the trees show unmistakably that they have passed their prime. I have, therefore, issued directions that all such plots shall be coppiced. But, in order that there may not be too great a felling taking place at one time, I have ordered that the coppicing should be spread over several years.

I purpose taking advantage of the opportunity, which this change in management will afford, of confining to particular plots particular varieties of cinchona. At present all the different kinds are intermixed, and the result of this is that, as some kinds grow more quickly than others, those which are of slow growth have a tendency to get smothered. The harvesting of a crop of a mixed plantation is attended also with more expense than is that of an unmixed one. Perhaps a still more important reason for keeping the different varieties separate is that, while at present the statements which are made of the number of any given kind of cinchona on an estate are little more than guesses, I shall in the future be able to inform Government very exactly.

C. Carthagena cuttings were planted out below the new storehouse, and are doing well.

Eighty-four thousand five hundred and thirty-nine plants were planted out, besides 15,987 as renewals. The young plants of 1882-83 did extremely well, and the plots are really in a very fine condition. I regret, however, to have to report that the planting in "Denison" No. II. proved almost an entire failure owing to the depradation of sambur. I have now erected a wire fence round this block, and therefore hope that the current year's renewed planting will prove as successful as were those of the previous year in the other plots.

I may remark in passing that the *Cinchona succirubra* in the year under report blossomed to a very small extent in comparison with previous years.

Hooker.—This estate, which in past years has been sadly neglected, presented so deplorable a condition that I proposed that it should be abandoned. As, however, it was thought that this proposal might have been made upon conclusions arrived at too hastily, it was decided that it should be retained, and I have, in accordance with this resolution, commenced the renovation of the plantation. Owing to a severe hailstorm in April 1883, which stripped them of all their leaves, nearly the whole of the *C. succirubra* were so injured that they had to be uprooted at once in order that the bark upon them might not be lost. The land upon which these plants stood has been pitted, and I propose replanting it with *C. robusta*, a variety which has proved itself to be more tolerant of cold and wind than *C. succirubra*.

One hundred and ninety-one thousand plants of *C. officinalis* were planted out during the year; of these, 104,740 were renewals. But, as the trees amongst which they are planted are so few in number and so meagre, these may very fittingly be regarded as "new plantings" also.

Speaking generally, this estate is greatly exposed to wind from the south-west; to mitigate the evil effects of this, I propose to protect the worst parts with thick shelter belts of *Frenela deltoidea*.

We should like to know if the shelter plant referred to is indigenous to Ceylon, and likely to make good shelter belts at our higher elevations? It will be seen that sambur (our Ceylon elk) do great damage to cinchonas on the Nilgiris. We proceed with our extracts:—

Wood.—This estate, like the last, has been sadly neglected. It has also greatly suffered from the ravages of sambur. I proposed that on this account it should be abandoned, but as this suggestion was not approved, I have commenced its renovation, and I hope in two or three years to make it a valuable estate. Its position with respect to the winds of the south-west moosoon is more favorable than that of Hooker, and the soil in many parts of the estate is deep and rich.

I have placed a rough fence round the whole of the plantation, and this, with the occasional help of a shikari, will, I hope, be sufficient to keep the sambur away.

At the present time there are very few old trees on the estate, and those which do exist are in so unhealthy a condition that the yield of bark from these will be extremely small.

I purpose disregarding altogether the trees which are at present standing and intend planting in broad stretches, the following varieties, viz., *C. officinalis* in the higher parts of the estate, *C. magnifolia* and *C. robusta* in the more exposed and less rich soils, while on the best and more sheltered and lower parts of the estate I propose filling up with *C. ledgeriana*, *C. morada* and *C. verde*.

Ninety-nine thousand five hundred and sixty-six plants were put out on the estate during the last year Of these, 95,743 were first plantings, *i. e.* they were planted upon those portions of the estate where the original cinchona trees had been uprooted. The remaining 3,823 were renewals.

It will be noticed that Mr. Lawson speaks of *C. pubescens*, *C. robusta* and *C. magnifolia*, the latter name, if we recollect aright, having been deprecated by Dr. Trimen, to whom, by the way, there is the following reference in the report:—

DR. TRIMEN'S VISIT.—In May last Dr. Trimen, Director of the Royal Gardens, Peradeniya, Ceylon, was invited by the Madras Government to visit Ootacamund, in order that I might confer with him on certain vexed questions relating to the names of some of the varieties which are grown on these hills. We went over all the estates in company with Dr. Bidie and Mr. Gass and examined very carefully all the trees about which doubt existed. The result of our inspection was that we were able to settle most of the questions, and this has already been made known to you in Dr. Trimen's Report dated 30th June 1883.

We notice in the accounts that a sum of R453 and 2 annas was paid to our Director for the travelling expenses of his visit. There are details about upkeep, including wire fencing for parts of Nadavatum infested by sambur deer and cattle. A great deal of manure, chiefly cattle-dung and poudrette, is applied to the cinchonas with obvious good results, except in the case of some artificial manure (bones and poonac chiefly). Bark from the trees so treated was to be analyzed, however.

Mr. Lawson's report proceeds to state :—

NURSERIES—*Dodabetta.*—Thirty-nine thousand plants and seedlings as per margin were sold to the public, and 650 plants were sent for experimental purposes to Malabar and Mudamalai. 94¾ lb. of cinchona seed were sold to the public. A large quantity remained on hand at the close of the year under report.

All of this I had destroyed, as towards the end of the monsoon I found that it was being attacked by weevils and mould.

Naduvatam.—Thirty-six thousand plants and 339,000 seedlings were sold to the public. Besides the above, the following plants were supplied to the Forest Department for experimental purposes at Calicut and Mudumalai :—

800 *C. pubescens.*
750 *C. succirubra.*
550 *C. calisaya, var. ledgeriana.*
10 *C. carthagena.*

390 lb. and 4½ oz. of cinchona seed were sold to the public The great demand of the past year was for seed of *C magnifolia* and *pubescens.*

Hooker and Wood.—The nurseries on these estates were well stocked with plants and seedlings, which will be used for replanting up the decayed portions of the plantations.

CROP.—The total crop of all four estates amounted to 186,652 lb. of dry bark including 2,887 lb. of bark, the balance on 31st March 1883.

Details are given and then Mr. Lawson proceeds :—

Dodabetta.—The crop for the year under report was the largest harvested since the beginning of the enterprise. The cause of this great increase is due to the fact that I coppiced two blocks (Nos. V and VI). I did this because I found that the trees on these tracts were very sickly, and it appeared to me certain that they would shortly die.

Fifty-two thousand two hundred and forty-three trees were operated on as follows :—

Stripped	... ...	44,623
Shaved	... ...	459
Coppiced	... ...	5,604
Uprooted	... ...	1,557

The difficulty of obtaining moss in sufficient quantities is yearly increasing, and, considering that in a few years more very many private estates will come into bearing, I have turned my attention to the shaving system, and which I hope will prove successful.

We notice in the accounts that "collection of moss" in the one month of October 1883 cost R483, expenditure which present prices of bark will not justify.

Mr. Lawson proceeds :—

Naduvatam.—The crop for the year amounted to 97,152 lb. This was collected from 22,830 trees, which were treated as below :—

Stripping System..	50
Coppicing ,, ...	9,330
Uprooting ,, ...	13,179
Shaving ,, ...	271

Hooker and Wood.—The chief system of harvesting was by coppicing and uprooting.

In the former estate 6,872 trees were uprooted owing to the injury caused to them by the severe hail-storm which occurred in April as stated in paragraphs 9 and 32.

The bark was disposed of as follows :—

	Lb.
Shipped to the Home Market	30,510
Supplied to Bombay Medical Department..	1,000
Local Sales	62,616
	94,126
Balance on 31st March 1884 ..	92,526
Total Crop ..	186,652

There were three sales by public auction at Madras during the year, namely, in December, January, and February when 62,616 lb. were sold. The prices realized on each occasion were very much lower than at any of the former sales; *e.g.*, the upset price in the December's sale of "renewed crown" bark was R265, the reduced price R199, and even then the bark was bought in. In the January sale the upset price was R182, the realized price R136 as against R265 realized in the first sale. In every description and variety of bark the fall in prices was very great and I feared that the sale of bark in Madras would have to be discontinued on account of failure. Since then I have learnt that the low prices which were obtained were due entirely to the great fall which had taken place in the value of bark at home, and that, when compared with the prices realized in England, those obtained in Madras were satisfactory.

It would appear that there were several causes operating which resulted in the fall in the value of bark :—

1*st.*—The enormous amount of cinchona which is now grown in all suitable parts of the world has brought about the natural result of making bark cheaper.

2*ndly.*—For advantages, supposed or real, to be gained, the manufacturers of the cinchona drugs have of late (as will be seen from a letter from Messrs. Oakes and Co, quoted below *) been preferring to buy South American rather than Indian barks.

3*rdly.*—The manufacturers, being few in number, have been able to restrain the market.

The first cause of the depreciation of the value of bark cannot but be a source of congratulation to Government, while the two last might to a large extent be obviated in the future by the establishment of a manufactory for the extraction of cinchona alkaloids in this country, and by using every possible means for the extension of the market for a cheap febrifuge in those parts of the Indian Empire which are most afflicted with malarious ailments.

All—even the poorer classes of natives—are becoming acquainted with the efficacy of quinine as a febrifuge and seek for it greedily; but the present price of the alkaloid is far beyond the reach of any but the rich, and therefore, before cinchona can be brought to the doors of the many buying poor, some method must be discovered by which the medicinal virtues of the bark may be extracted in a manner that shall render the sale of it cheap and at the same time be profitable to the grower. Pending the discovery of such a method, I would suggest, for the consideration of the Government medical experts, whether it might not be of advantage to supply the local dispensaries with crude bark to be used, as it was in old times.

I regret to report that the packing presses which were bought from Messrs. Groves & Co. are not giving as much satisfaction as might be desired. The bark is packed more quickly with less expense and in better form by the old system of wooden boxes and rammers.

Then follow details of buildings, including drying sheds, &c. Figures are given, showing that less than 10 per cent of trees coppiced failed to sprout, a much better result, we believe, than is generally obtained on most places in Ceylon. There was also a recoppicing after an interval of 10 years. The result was most satisfactory, but the young shoots were destroyed by sambar. We quote again :—

Several experiments under the various systems of cropping were carried out, the results of which are being noticed and recorded. Samples of bark from each tree under each system are being retained at the office for analysis by the Quinologist, who is expected shortly. The results will be reported to Government in due course.

LABOR.—Laborers were plentiful on all the plantations, but a large number of the more experienced Canarese coolies were enticed away by the high wages which were paid at the gold mines of the Wynaad.

FUEL SUPPLY.—The different shoals upon which the estates have been hitherto dependent for fuel are now nearly

* Messrs. Oakes and Co.'s letter dated 27th February last.—"After Monday's sale we undertook to wire to you the offers received for the unsold lots, but at the same time expressed our opinion that the seriously reduced prices of bark as represented by the offers would probably be unacceptable to the Government, and in any case would prove a discouragement to the holding of further auction sales, which had hitherto proved greatly to the convenience of manufacturer's agents here and profitable to the Government as compared with the result of the shipping the produce to England. Our opinion appears to have been telegraphed to Europe, and a reply has been received today resulting in the enhanced offers accepted by us. We are convinced that the prices are considerably above the parity of price of cinchona bark in Europe, and are naturally gratified at the result."

exhausted, and in another two years at the furthest I shall have to buy. I am therefore replanting the shoals with *Eucalyptus* and *Acacia melanoxylon*, with the view of making the estates again self-supporting in this respect as soon as possible.

SEED.—I received at the beginning of the year many complaints from the purchasers that the seed which they had bought during the previous year was bad and that a very small portion of it germinated. The cause of the badness of the seed was probably due to its being carelessly picked off the trees and to its being dried at too high a temperature in the drying shed. I have no doubt but that the excessive severity of the monsoon during the harvesting season in that year was a great difficulty and not properly allowed for. To prevent a repetition of this evil, I have laid down special rules for gathering and drying the seed, and there will for the future be no difference in the quality of the seed which is sold to the public and that which is used for the purposes of the estates.

Finally :—

AMSTERDAM EXHIBITION.—I have to record that the authorities acting on behalf of the Amsterdam Exhibition awarded the gold medal to the Madras Government for the best collection of specimens of cinchona, or rather that they thought that the collection deserved a gold medal, but that, if the Madras Government desired to have the medal, they must pay for it the sum of £20.

The medal was presented by Government to Mr. Gass, whose past careful attention to everything connected with the cinchona estates rendered him well worthy of the honor.

Then follow the figured statements, and the Order of Government, the tone of the latter showing approval. We notice that nearly 2 lb. of bark (green, of course) per tree was obtained from *C. officinalis* stripped and mossed on Dodabetta, and 6 lb. from trees uprooted. *C. succirubra* trees coppiced on Naduvatam seem to have yielded 21 lb. per tree ; officinalis about 6½ lb. ; Calisaya about 7 lb. Uprooted trees gave less, no doubt because of their sickly state. The green bark dried from a little over ½ down to ¼. The Order of Government notices, that under Mr. Lawson's new system, hybridization will be avoided, as if that were a desirable result, which we doubt ; for on good hybrids the future success of cinchonas in South India and Ceylon seems largely to depend. The Madras cinchona enterprize has well paid directly as well as indirectly, as witness the following paragraph from the Order of Government :—

The statement of Capital and Revenue account appended to this review shows the financial results of the cinchona enterprise from its commencement to the close of 1883-84. The net result is a surplus of R6,31,489-12-7. In this statement credit has been taken for the value of products manufactured in England at market rates as ascertained from the Examiner of Medical Accounts, less cost of freight, manufacture, &c., as advised by the Secretary of State. The reasons for the adoption of this course were given in the order reviewing the report for 1882-83. No credit has been taken in this statement for interest on receipts, as was erroneously done in former years, while on the charges simple interest only has been allowed for in lieu of compound interest as hitherto. This mode of calculation is in accordance with the practice of the Public Works Department in regard to remunerative public works, and is obviously sounder and more accurate than the method hitherto in vogue.

With nearly £60,000 to the good, the Madras cinchona plantations are thus a great success notwithstanding present low prices.

SALT FOR AGRICULTURAL PURPOSES IN CEYLON.

Surely the time has come for relaxing the exceedingly stringent regulations framed to protect the Ceylon Government in their salt-tax monopoly, so as to admit of the valuable fertilizing qualities of salt being utilized by our farmers and planters? We need not recur to the enquiry and correspondence of some years ago when the Planters' Association were refused permission to use salt for mixing with manure, on the ground that, however mixed or debased, the saline product could be separated so as to be availed of as a condiment with food. Practically we cannot see how such separation and purification could be undertaken even by estate coolies, after a thorough mixing with manure under official inspection provided, of course, at the expense of the merchant or planter.

Be that as it may, some provision is urgently required by which both native and European agriculturists may use a fertilizing material which nature has provided so lavishly and cheaply. A very hard case has just come under our notice which, we trust, will be the means of inducing Sir Arthur Gordon's Government to consider the whole question. The well-known native Pettah firm of Messrs. N. S. Fernando & Co. have been enterprizing enough to import from Chemical Works in London some eight casks with over two tons of "Rock Salt" intended to be mixed with bone-dust for sale to paddy cultivators. Mr. Fernando assures us he had previously proved the great value of this fertilizer, and that there is a ready market among his intelligent countrymen for such a mixture to be applied to their fields in favourite rice-growing districts, as also to coconut plantations. Though the name is pleasant enough to lead one to expect a very pure article, "rock salt" in reality is a manufactured compound with a very unprepossessing odour very unlike food salt. To endeavour to place himself right with the Customs, Mr. Fernando had his "rock salt" examined, with the following result :—

Temple House, Maradana, 19th October 1884.—I certify that I examined a specimen of salt sent me by Mr. N. S. Fernando and that I found it to be what is known as "rock salt." There is so much impurity organic and inorganic in it, that it is not fit for culinary purposes. It is usually utilized as manure.—THOMAS F. GARVIN, M.B., *Public Analyst*.

Rock salt costs laid down in Colombo about R30 per ton ; but at the monopoly rate of duty, imposed to guard against foreign competition with the salt prepared and sold by our Government, the Customs demand for duty will be equal to R41·30 per ton or over 130 per cent on the cost price ! This, of course, is simply prohibitory, and Mr. Fernando is accordingly applying that "rock salt" under the above certificate should either be admitted free as a manure or charged not more than five per cent *ad valorem*. If this concession is not made, of course the importation will cease, and native cultivators especially will lose the benefit of a very suitable fertilizer for their crops. We trust, however, that not only will Mr. Fernando's application be granted, but that the Government may see their way to allow salt generally to be manufactured into a manure under proper inspection. By that means a boon of no ordinary value would be conferred on the agricultural interests of the country.

CEYLON UPCOUNTRY PLANTING REPORT.

COFFEE PICKING : QUALITY AND ESTIMATES—LEAF-DISEASE AND HUO—CACAO : EFFECT OF MANURE—CACAO ON THE NILGIRIS—VALUATIONS OF ESTATES—VISITING AGENTS—THE TURN OF THE TIDE—GROWTH OF TEA—1,200 LB. PER ACRE EXPECTED FROM MARIAWATTE—NATIVE GARDENS AND CHETTIES.

12th Nov. 1884.

On the lower estates picking for the last ten days or so has been almost at a standstill. The results of the first blossoms have been gathered, and there is now a lull until the others ripen up. The quality of the coffee, I am sorry to say, does not improve much, light and unformed beans being much too prominent, the rain coming too late to remedy these evils.

As to estimates—well, the first half and more has been secured, but the difficulty always comes in with the other half. Whether that difficulty will be surmounted remains to be seen : some doubtless will overcome it—happy people—others won't.

Of course the season has been a very unfortunate one, making the wild guessing (which in these days is called estimating) more hazardous than ever ; indeed, what with the results of drought and bug it could not have been worse. And then the wretched state in which the bug has left the coffee. Leaf-disease in its worst days never produced such a ghastly spectacle, for the coffee stands blackened and gaunt, unresponsive alike to the powerful stimulus of manure and digging, or the more gentle influences of rain and warm sunshine, and *will not* be clothed. The appearance of a field of coffee stricken in this way was graphically put to me by another when he said, "You could see a hare for a mile through it." And yet some tell us it will recover, insisting that some low estates which last year were very bad have improved this, and are going on improving. One's faith in these days is often put to a sore trial, and to stand by the wreck of what twelve months ago was really good coffee and to see in its blackened branches and bug-covered twigs the potentiality of future fruitfulness is a case in point. It is a hard task indeed, and I sincerely wish that those who have never been tested in this way never will. Cacao still keeps throwing out blossom, and looks well. Its wonderful fruitfulness in suitable situations is undoubted, and even where soil and exposure are not everything that can be desired, it makes an honest fight to respond to the care bestowed on it. I have heard of a cacao tree on an estate not far from Peradeniya on which 400 pods had been counted. A grand result, without doubt: whether from the effects of manuring I cannot say, but I knew of nothing which profits so much by liberal treatment as cacao. On it, manure acts like a charm.

The success in Ceylon of this new product has encouraged some of the Indian planters to try it there, and an estate in the Nilgiris which imported seed from Ceylon has found cacao to do remarkably well. As there is a good deal of land in that part of the world suitable for cacao, and it is already attracting attention, we may hear of an Indian rush for cacao pods, which Ceylon will be only too glad to supply.

The days of fancy values for coffee estates do not seem quite to have left us, when one hears that a visiting agent estimates a coffee estate in Maskeliya on which tea can be planted at R150 an acre. I do not desire to say a word to depreciate property, still it would be interesting to know on what principle such a valuation is based.

In the days when coffee was inflated to the bursting point, these all-powerful people known as V. A.'s went round the country bidding against each other in the valuing of estates, making marvellous calculations which produced marvellous results. Alas ! however, as it turned out to be more or less in the fancy line, until they reached the climax of being fairly staggered themselves, and the end came. Then there was the rush in the opposite direction, and the first to take the plunge did well. To depreciate was the chief end of them, and how nobly they responded to the call, and carried that mission out, many a sad heart can tell today.

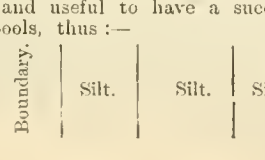
The tide, however, has turned again, and, although "one swallow does not make a summer," still it is cheering to get a valuation in the temper and tone of the old days, and to recognize that there is a heart of hope left, and, as the Americans would say, that the "boom" is coming.

I hope to hear of more valuations of this kind, and somewhat envy the district of Maskeliya that it should have been the first to have been honoured. It was for land suitable for tea. How much that covers is the point, for it grows almost anywhere. One who has unbounded faith in this new product asserts, that, if it were stuck in the public road, in the hole made with an alavanga, even then it would be a success. To these lengths have we gone already ! While on this subject, I may say that I learn that Mariawatte has cured 1,050 lb. of tea per acre to the end of last month, and that the 1,200 lb. is expected ere the year expires. Is R150 an acre for land suitable for tea out of the way after all?

The small native gardens, which in the hands of the original proprietors turned out to be a snare and a delusion, landing them deeper and deeper in debt, have not done any better for the Chetties into whose hands they ultimately fell. Sharp as the Chetty is, and willing as he may be to work for a very small return, coffee has over-matched him, and he is bound to admit that he is beaten. About Gampola there are a number of gardens of small extent which the Chetty proprietors are endeavouring to transfer, for a consideration of course, only buyers are scanty.

THE ACTION OF COFFEE on the composition of the blood, as well as on the digestive functions generally, has been the subject of research with three French chemists—Messrs. Couty, Guimaraes and Niobey. They find that coffee acts beneficially in stimulating the consumption and digestion of the nitrogenous elements in human food.—*Australasian.*

PRESERVATION OF SOIL ON HILL ESTATES.—The superintendent of an estate in Dimbula which has a good many steep features on it, and where the system of close planting on such steeps and of tea *hedges* along roads and drains is being carried out, writes :—"Your article on 'Terracing' was A 1. Perhaps you might have mentioned our building bunds at the edge of the boundary, to catch all soil. They have answered splendidly." As we said in our article, a certain amount of "wash" cannot possibly be avoided, but the detrimental effect can be minimized by the adoption of a system of abundant roads and drains of easy gradient generally such as we indicated, supplemented by the bunds to which our correspondent refers, and which did not occur to us when writing, although we took a personal interest in their construction. The drains run, of course, into ravines, and the waters of several ravines join in main streams as they flow down. At the outlets of such streams (we are not writing of rivers but of river-tributaries) from the lower boundary of the estate, all timber and loose soil were cleared away and utilized for manuring the bushes in the neighbourhood. The stones available were then used for the construction of bunds near the boundary, sufficiently strong to resist ordinary floods, the waste water, after depositing, as silt, the earthy particles with which it comes laden, flowing over the top of the bund. Periodically the bunds are opened and the lakelets of water allowed to escape. The deposit is then collected by the coolies and applied to the tea-bushes. In very exceptional floods, a breach may occasionally be made in the bunds, but no great harm is done, as much of the settled silt is not carried away, and on the whole the system of bunds, as our correspondent states, is a great success. In ravines, wide and through which copious streams flow, it may be necessary and useful to have a succession of bunds and silt pools, thus :—



"HELOPELTIS" IN EXCELSIS.—We have received from Peradeniya a small sample tin box crammed full with Helopeltis, the result of 4 cooly boys' efforts over 30 acres of cacao for two days! Anyone desirous of becoming familiar with the insect or seeing it in the mass can do so at our office.

TEA MACHINERY occupies a good deal of attention in our community now, and we are sure to have new contrivances and improvements year by year. The agent for a large Lincoln firm of manufacturers is at present in the island and is interested in learning how Ceylon planters go in for patents on their own account. The latest report is from a correspondent who writes:—"I hear that a well-known Dikoya planter has invented a new tea-rolling machine and also a drier. We shall soon have plenty to pick and choose from."

TEA SUPERSEDING COFFEE IN FIJI.—A correspondent of the *Fiji Times*, writing from Bua, states:—

Nawi was another European settlement situated on the bank of the Bua River. This place has been bought back by Tui Bua, and is now his own personal property. If he would purchase back all the blocks of land he has sold to the whites he would rejoice the hearts of many. Mr. Wilkinson sticks to the old place—grows coffee at Kadi, and runs cattle at Wailailai. Kadi, the last time I saw it, looked well. I have seen several of the coffee estates in Fiji, but neither of them, in my opinion, equals Kadi as I saw it some years ago. Mr. Wilkinson has a very perfect coffee curing establishment at Wailailai where the coffee is hulled, and sized, and prepared for the market. All the machinery is driven by steam power. Rain is much wanted at Bua and indeed on the whole of Vanua Levu. Everything is languishing for want of the refreshing showers. Only two inches of rain have fallen since the 20th of April. The grass is brown and dry and bush fires are of frequent occurrence. Wainunu appears the most lively part of the Bua province. The coffee estate of Messrs. Sharpe, Fletcher & Co., situated in the locality, has just changed hands—Messrs. McKinnon and Barret are the purchasers. It is reported that these gentlemen intend to pull up all the coffee and plant tea. They have had considerable experience in the cultivation of the tea plant in India, and have every confidence in the soil and climate of Fiji, and think both are admirably adapted to the profitable cultivation of tea. Everyone, I am sure, will wish them success in their operations.

Again the *Fiji Times* states:—

The Messrs. Martin Bros. of Wainunu, have decided that the Government and the Immigration office is too strong for them, and they have therefore sold out their coffee estates, at a very considerable loss, to Mr. Simpson, a comparatively new arrival, and propose quitting the colony by the Hero. The last straw which broke the camel's back was a conviction before the local magistrate for neglecting to weigh out food to the house servants, who fed from the employer's table, accompanied by an intimation from the bench that these women (who had been engaged specially as house servants) should not be set to work before 7 a.m.; should have the full hour in the middle of the day; should cease work at 5 p.m.; should have a half holiday on Saturday, and entire holiday on Sunday, as though they were field hands. Having a wife and a family of eight young children Mr. Martin turned the matter over in his mind, and decided that under such conditions perhaps Sir Arthur Gordon was right in saying:—"This is not a white man's country," therefore he leaves it. It is to be hoped that Mr. Simpson will be more successful. He proposes to follow the example of his neighbours, Messrs. McKinnon and Barret, and grow tea. He has every natural advantage in his favour, climate, soil, position, and if allowed to succeed his success should be certain.

CORIANDER SEED.—Messrs. W. H. Davies & Co. write:—"In your last Commercial Letter from London, the writer refers to Coriander Seed, and says he does not recollect having heard of this article of import from London. It will interest him and perhaps others to know that many shipments were made from Ceylon to London in 1883."

HELOPELTIS AND OTHER PESTS.—A planting correspondent writes:—"I think a great deal too much has been, and is being, made of our enemies. This seeming constant discovery of pests is doing more harm to Ceylon at home, I fear, than the whole of the pests put together." We have already endeavoured to guard against unwarrantable inferences among home capitalists and others from the constant discussion over pests on new products in Ceylon. No branch of agriculture is free from troubles of this kind, and the country where they are most discussed ought really to be the safe one for investors as shewing that those concerned are doing their best to study the nature of and the remedies for such evils.

TEA IN CENTRAL ASIA.—The efforts to introduce the teas of India into the markets of Central Asia through Yarkand and Ladakh do not seem to be approaching much nearer to success. From the recent Report on the external trade of the Punjab, it would appear that most of the tea which finds its way from India to those regions is actually Chinese tea which has been imported to India by sea, and is then sent out again on its difficult way through the Karakoram or some other of the northern passes. Through Kulu alone 184 maunds were dispatched during the year, valued at R150 a maund; but the Central Asian palate which puts so high a value on brick tea, *gola cha*—tea, that is, made up into balls with rice-water—and other abominations, retains a perverse indifference to the choicest leaf of Kangra and Kumaon. The sound but humiliating advice which is offered to the Indian planter under these circumstances is that he must study Chinese methods of manufacture, or rather of adulteration, if he would seek the custom of Central Asia!—*Pioneer.*

A CHEAP ROTATING TEA ROASTING MACHINE, *à la* Gibbs & Barry, but simpler and therefore far less expensive, is noticed by the veteran Indian tea planter, Mr. S. E. Peal, in a letter to the *Indian Tea Gazette*, thus:—

Small estates cannot make a "break" of P. or P. S, or B. P., under a week, say 20 chests of each kind, we should thus have to "Binn" our teas after sifting, and final fire the break after bulking it. But 20 chests is now-a-days too small, and 50 chests more what is wanted by dealers. Now in a small estate making, say, 10 maunds per day, there are on an average some 40 chulas, or 50 at outside, and to pukka-bati 50 chests (or 6,000 lb) of B. P. (allowing 20 lb. to each tray or dhol fire) needs 300 chulas! and the work to be done at night, or on off-days—as Sundays. But even let us say there are 100 chulas in our tea house, it would need three *days* to do the 6,000 lb. in, unless we stopped all our usual work. So to bulk, final fire off, and pack hot, large lots, or even moderate ones, of 50 or 60 chests, on small estates, is impossible, with the drying facilities we usually have,—dhols, chulas, typhoons, or siroccos. To get 50 or 60 chests, bulked, we should need to "Binn" our teas daily as sifted, till we got our 6,000 lb., say, of one class, and then have all out of bulk and final fire at once. Properly we should fire first, and then bulk and pack "all hot" after; but our drying capabilities are generally ten maunds tea per day (not 60.) It is no use recommending siroccos—G and B at R4,000 or new Jackson's; we need a machine for *small* pockets and big breaks. The only one I see at all likely is that patented by the late J. Scott of Rajmai, *i.e.*, a rotating cylinder *à la* G and B, but without all that costly girder and gearing, and simply slung and driven by a wire rope from an overhead pulley above one end. The fan drives cold air through the fire, thereby having less than one-sixth the work to do, and with cold bearings; such a machine small estates could buy, as it is only about R1,000, and does fully as much as a G and B dryer, or new Jackson and is as simple as cheap, and equal to 50 maunds a day.

THE INDIAN GARDENER:

A FORTNIGHTLY JOURNAL OF HORTICULTURE IN ALL ITS BRANCHES.

We some time ago acknowledged receipt of the first number of this interesting journal. The introductory article states:—

The necessity of a journal devoted to Horticulture, in all its branches has, we believe, been generally felt by those who take any interest in Gardening in India; and it seems strange that hitherto no attempt has ever been made to supply this want. The Tea Planter, Indigo Planter, Agriculturist, Sportsman, the Clergy, and even the Medical Faculty, each have their own special Journal, and yet the one pursuit that dates back to the days of Adam—that gives unlimited pleasure alike to rich and poor, to all creeds and colours, that forms also a means of health-giving recreation to those who take an active part in its pursuits, that surrounds our homes with beautiful objects, forming a cheerful and pleasing panorama on which the eye may always rest with delight and never weary in doing so, bringing in fact the noblest and most sublime works of the whole creation to our very doors,—

> Where'er we turn our willing eyes
> Some floweret sweetly beams,
> Some spirit breathes congenial sighs,
> And earth the richer seems;

and last, but not least, supplies us with a large share of daily food—this, of all others, has been left neglected and uncared for; doomed to struggle on, unaided by any organ to proclaim either its beauties and unlimited resources, or to assist the uninitiated and unlearned, not only in giving the knowledge essential to success, but also to induce him to take an increasing interest in its studies.

The many English Gardening Periodicals are undoubtedly of great value in keeping us well informed regarding the hosts of new plants that are being continually introduced; but as a guide to the practical part of the work pertaining to a garden, are of little value to the resident in this country, where we must adopt special means and measures to meet the difference in climate and seasons. Another drawback to some of these journals being of much practical utility to the amateur, is the fact that many of their contributors write as it were from a lofty pinnacle, giving forth their knowledge to the world emblazoned with every possible botanical term, when their meaning could frequently be much better expressed in plain English, forgetting, of course, that the majority of their readers have not had the opportunity they had probably enjoyed of continually feasting on the works of our most eminent botanical authorities without restraint.

It will be our constant aim to avoid falling into this error, and we shall studiously endeavour, at all times, to say what we have to say in a plain practical manner, avoiding the use of all superfluous Latin terms and technicalities, believing that in so doing, we shall be studying the wishes and interests of the majority of our readers, and consequently, at the same time, our own. In no pursuit or avocation is the old adage of "an ounce of practice being worth a pound of theory" more applicable than to horticulture, and in dealing with the multifarious subjects that will appear in our pages, the object will always be to give practical results rather than to propound new theories.

There is a good article on Horticulture in India, from which we quote as follows:—

Another drawback, is the difficulty, we might almost say the impossibility, of procuring really skilful labour, although it must be admitted that the native *mallee* has improved almost to as great an extent as our gardens, since the days of Firminger, his infirmities or vices, however, have kept pace with the development of his abilities. From our own personal experience, we should say "carefully avoid the very clever Mallee," and especially so if he shows any great ability in acquiring the names of plants committed to his charge, for in almost every instance we may be assured that the knowledge thus acquired will be used to his own pecuniary advantage, and not for the benefit of his employer. In support of our opinion, we may mention the fact that some of the proprietors of our leading nurseries make it a practice to change all their gardeners every six or twelve months, or at least before they have acquired sufficient insight into the value of plants to enable them to use it as a source of profit to themselves.

Under the head of Ornamental Foliage Plants, the Croton receives elaborate treatment. We quote as follows:—

The Croton still stands out pre-eminently as the plant of plants for our Indian gardens; and notwithstanding the immense number of new species and varieties of other plants and shrubs that have been introduced since the Croton first found a place therein, it is doubtful if amongst the whole of them a more generally useful plant can be found. It thrives both in sunshine and shade, and not being fastidious as to soil, it can be used almost in any situation. Planted out however in the ground in a partially-shaded spot, it is seen to most advantage; and where it has room for full development, attains a large size. A well-grown Croton properly coloured is indeed a beautiful object, and has this advantage over flowering shrubs that it retains its beauty throughout the year. For associating with other plants in shrubberies, borders, or beds, it is also well adapted, and by a careful use of the knife, it can be easily kept in bounds, without in any way impairing its beauty, by giving it a trimmed-up appearance.

In a long article on the culture of the Dahlia, it is stated:—

There is, however, a course by which the Dahlia may be grown by us in all its beauty and perfection, and it is such a simple one that the wonder is that it has not been generally adopted years since. *This is to procure the tubers from Australia*, where nearly all the best English varieties can be easily obtained; their season of rest there, which is from May to October, exactly adapts them for this country, and if tubers are ordered to be despatched by the end of August, they will arrive here in good time for planting out at the end of October or early in November. We have tried this experiment for some years, and with unqualified success.

Pansy or Heartsease is also the subject of a long paper. An article on Orchids is specially full and interesting commencing thus:—

It is less than a century and a half ago that the first species of epiphytal Orchid was introduced into England by Rumphius, from the island of Amboyna, in the Indian Archipelago, previous to which the glorious luxuriance of our tropical forests with their innumerable species of wonderful fungi, lichens, filices, epiphytal, and other plants, had often been related by eastern explorers, but little credence was given to them; and it was not till that lovely orchid *Phalænopsis amabilis* was introduced in 1763 that the botanical authorities of the time would condescend to believe in the reality of epiphytal plants, or even to notice them in their works. Gradually, but surely, however, from the commencement of the present century, the number of species introduced has continued to increase, till at the present time there are upwards of four thousand known varieties. It was not, however, till about twenty years since that any very great interest was evinced in their cultivation in Europe; and now it seems probable that it will become almost as much of a mania in England as the cultivation of the Tulip was in Holland some two centuries ago. During the past two or three years several large private collections have been disposed of at home by auction, and have realized sums varying from five to ten thousand pounds, individual plants realizing from one hundred to one hundred and eighty pounds each.

It is shewn that the sub-ranges of the Himalayas are especially rich in these curious plants.

Again:—

In its native habitat it is remarkable how much the flowers of different plants vary in depth of colour. A writer, speaking of *Saccolabium paniculatum* found in this locality, says the white variety is exceedingly pretty, bearing a single spike, whilst *rubrum*, a variety of the same, is often branched. I am inclined to think, he says, that the difference in these two plants is caused by the different elevations at which they are found; low down it is nearly white, increasing in depth of colour as the higher altitude of 6,000 feet is reached.

Residents in Ceylon must have noticed this variation in the blossoms of the common parasitic plant *Loranthus*. The blossoms in the lowcountry on the damp south-western

coast bear a strong resemblance to the yellow of honeysuckle flowers. But equally in the dry climate of the east of the island and at high altitudes on the mountains, the blossoms are of a rich ruby red colour.

The article on Climbing Plants we quote as follows:—

In the extreme beauty and immense variety of their climbing plants, either indigenous or acclimatised, our Indian Gardens undoubtedly compare favourably with those of almost any other part of the world, and when these are properly cared for, and utilised to the best advantage, certainly form one of its chief attractions. We must, however, reluctantly admit that we have had to give up the unrivalled *Lopagerias* in despair, and also that we cannot induce the *Dipladenias* to bloom so freely or grow as vigorously as we could desire; still these failures are more than compensated for by our gain in other directions. Take for instance the whole Antigonon family; all of these bloom most profusely with us nearly all the year round, and yet during the many years they have been cultivated in England have never been known to flower except on one occasion, this being, if we remember rightly, on a plant in the possession of Mr. W. Bull, the celebrated plant merchant.

The majority of creepers require but very little attention to induce them to thrive satisfactorily. Give them a good rich, open soil, in a well raised situation, and with plenty of space to ramble at will, and they never fail to succeed. Stiff screens, wire trellises, and such like arrangements, are all very well for certain positions or occasions, but they are certainly not the means we should employ to show most of our climbers to advantage. The nearer we assimilate the treatment of plants to what they are accustomed to in their natural habitats, the more sure we shall be of success. The natural support of all climbing plants are trees of larger growth, let us therefore endeavour to give them the same. As an experiment plant *Bougainvillea Spectabilis* or *splendens* at the root of a mango tree. In the course of a year or two its shoots will protrude through the branches in every direction laden with its bright coloured bracts, forming one of the most brilliant sights imaginable, without doing the least injury to its supporter, for although a very rampant climber, it is not of dense habit, *Antigonon leptotus* makes a splendid object when trained on the bare stem of a coconut tree. All the support it requires being about half a dozen strands of galvanised wire stretched tightly from the top to the bottom of the tree, with circular bands of the same about six feet apart, to keep them in proper position, leaving two or three inches of clear space between the perpendicular wires and the stem to admit of the young shoots passing freely around them. A plant grown in this way, when in full bloom, is worth going a long journey to see. We must not omit to mention a well-known, though sadly-neglected indigenous climber, namely *Batatas paniculata*, a plant that grows well in almost any situation. We have plants of this that have been growing for years on the edge of a clump of bamboos, and others, at the roots of some dwarf date palms. These never fail to grow vigorously each rainy season, almost entirely covering the bamboos or palms with their handsome digitate foliage, and for three or four months producing their glorious panicles of bloom in the greatest profusion. Appended is a brief description of some of our most popular and beautiful climbing plants:—

Allamanda nobilis.—This is undoubtedly the finest member of this genus; it is of very vigorous growth, with large handsome foliage borne in successive whorls on the stem. The flowers are from six to seven inches in diameter, of a very bright clear yellow, shading to deep orange in the throat.

Allamanda Schotti.—This differs but very slightly in form or habit from the preceding; the flowers, however, are not so large, and are of rather a deeper shade of yellow.

Antigonon leptotus.—This is almost too well known to need any description, being found in almost every garden. When in full bloom, with its enormous panicles of bright rose-pink flowers, forms one of the most brilliant objects in the whole vegetable kingdom.

Bignonia Magnifica.—A new variety of great merit; the flowers, which are of a bright purplish crimson, are produced in large branching panicles, the individual blooms being about three inches in diameter.

Bignonia Venusta.—This is one of the most gorgeous climbers in cultivation, and requires a large space for its proper development. The leaflets are oblong-ovate and acuminate, the leaves formed of two leaflets being in pairs along the stem. The flowers are produced from the axils of each leaf in dense drooping spikes or corymbs; each bloom is about two inches in length, trumpet-shaped, deep vermilion in colour. Flowers in January and February, and lasts a long time in perfection, entirely covering the whole surface on which it is trained with a complete sheet of colour.

Bougainvillea Spectabilis.—A very vigorous growing plant, requiring a strong trellis for its support, or a large tree as previously described, it bears immense panicles of large cordate bracts of a bright rosy-crimson, enveloping the whole plant in a mass of lovely colouring.

Bougainvillea Splendens.—A comparatively new variety, and certainly the most beautiful of the genus, in form and habit resembling the preceding, the bracts, however, are of a more brilliant shade of crimson.

Cissus discolor.—The most beautiful of all ornamental foliage climbers. When in a healthy condition, the exquisite tints and delicate blending of colours in the leaves almost defy description. Requires to be grown in a position entirely excluded from the sun.

Ipomea rubro cærulea.—One of the most beautiful of the Convolvulus family, though of a perennial habit can only be successfully grown here as an annual. It is of very vigorous growth—producing its flowers in immense profusion; these on opening in the early morning are of a bright azure blue gradually fading during the day to a dull reddish tint. The seed should be sown at the commencement of the rainy season, the plants will then be sufficiently advanced to bloom freely as soon as the cold weather sets in in November.

Ipomea Horsfalliæ.—A new perennial species of great beauty, flowers large and produced in panicles, of a rich deep shining rose colour.

Ipomea Leari.—A very beautiful species of robust habit, producing its intensely bright blue flowers in great profusion throughout the whole year.

Poivrea coccinea.—A very vigorous-growing scandent shrub covering a large space with its slender stems and bright green foliage, almost always in bloom: its minute deep crimson flowers being borne in large compact panicles. When well grown this is a very beautiful ornament to a garden.

Stephanotis floribunda.—One of the most highly-prized of all climbing plants; the leaves are ovate; leathery in texture, and of a rich shining dark green colour; the large pure white waxy-looking flowers are produced in clusters and are highly fragrant.

Tecoma jasminoides.—A very free blooming species of great beauty, with deep green pinnate foliage; the flowers are borne in corymbs, white, slightly tinted with pink, with deep purple centre.

Tecoma rosea.—A remarkably handsome new variety. It has opposite pinnate leaves with ovate leaflets, and bears magnificent racemes, upwards of two feet in length, of large, showy, trumpet-shaped flowers which are of a rosy lilac colour.

We add a couple of extracts:—

An excellent plan for preserving the beauty and vitality of cut flowers for a long period, is to add a very small quantity of salts of ammonia to the water in which they are placed, or a small piece of camphor, dissolved in spirit of wine, will answer the same purpose. Those of our readers who have hitherto been disappointed in their endeavours at arranging flowers, will, by carefully following the above suggestion, probably be agreeably surprised at the greater degree of success that will attend their efforts.

LIQUID MANURE.—Probably nothing conduces more to the success of the majority of vegetables than being liberally supplied with liquid manure. It is far more stimulating and quicker in its effect than heavy dressings of dry manure. The reason for this is obvious, as it is supplied in such a way that the plants are able to absorb it at once. It may be made from fresh droppings of the cow, horse, sheep, goat—in fact of nearly any animal. All that is required is to allow the water to remain on it for four or six days, so that, when it is used, it may be perfectly clear. Its strength, of course, must be regulated according to the requirements of the crops for which it is intended.

THE AMERICAN FRUIT EVAPORATOR AS APPLIED TO THE PREPARATION OF TEA, COFFEE, CACAO, ETC.

It is a good many years now, since, on receipt of an illustrated description of the American Fruit Evaporator, we pointed out through our columns the great probability of its adaptation to the purposes of a tea-drier. On several occasions, subsequently, we gave very copious details of the principles, construction, prices &c., of the machines. Those interested in tea, coffee and cacao, can now judge for themselves, seeing that Messrs. W. H. Davies & Co., of Colombo, as Agents for the American Manufacturing Company, are in possession of specimen machines. These machines, we trust, will soon be shown at work, for which purpose supplies of tea-leaves, cacao-beans and coffee-berries can be brought to Colombo The practical test is, of course, the only one which will satisfy planters. We are strongly inclined, from all we have read, to believe, that, as a tea-drier, the machine will prove a success; but we confess to being staggered when told that it is equally adapted to withering and "garbing" (sifting); that, in fact, while one part of the machine is engaged in withering the leaves, another with a heat of from 100° to 400° will be finishing off leaves which have been rolled and fermented! A machine which could simultaneously wither, sift and roast tea, would certainly be a valuable acquisition. Besides a pamphlet (copies of which have been for some time in our possession), we have now received an address by Mr. Victor Hollingworth Special Agent for the American Manufacturing Company, and formerly a tea-planter in Assam, addressed to tea, coffee, cacao, indigo, spice and cinchona planters and agents, in which it is stated that

While all sizes are available, for, and valuable as dryers I request you to note that the larger machines, Nos. 3, 4, 5, are more especially adapted for commercial use in factories of size, these being metal-lined, fire-proofed, and specially designed and equipped, a corresponding price being quoted for them. These machines will be fitted with wire cloth of any three sizes, when ordered for particular work, or if so specified with a proportionate number of each or any size thus rendering them available for a diversity, and succession of uses in factories where more than one work is performed, a feature which will commend itself to your notice, when compared with other dryers specially designed for one purpose, and whose utility is consequently prescribed. No. "4" (i.e, four meshes to square inch) is available for coffee, nutmegs, cardamoms and berries of approximate size, while No. "13," is adapted for tea, and broken substances of a similar nature, but it must be noted, that "tips," or small particles falling through the meshes, are not lost, burned, scorched or damaged, as they merely lie upon the floor of the "Trunk" till swept up. For substances of the consistency of indigo which lie close, and hold much moisture, a close woven wire cloth can be fitted, classed as No. "0," and the trays are well adapted with little alteration for evaporating all substances of this class by covering the wire with muslin, as is usually done, the philosophical arrangement of the hot air currents, not being affected thereby, and thus every tray is made available for special use.

We do not understand what is meant by No. 13, for, in the table given by Mr. Hollingworth of "American Pneumatic Evaporators," as adapted for tea, coffee, cacao, dye-stuffs spices, &c, we find (as in the Company's pamphlet) numbers only extending from 0 to 5. The prices of the adapted machines, we notice, are fixed a good percentage higher than the original fruit evaporators. For instance, No. 3 (for which, probably, No. 13 is a misprint), stands at $175 or say R430 in the original list, while here it is charged at $250, or say about R620. Full details are given regarding the six sizes, and we quote those attached to No. 3. The cash price in America will be the equivalent of about R800, and to this will have to be added freight at 60s per ton (we quote the figures given) of 1 800 lb. weight or 110 cubic feet, the number of pieces packed for shipment being 6, it being explained that

The packages above named as crated or boxed for ocean freights are susceptible of division into two, three or more packages of light weight for carriage over difficult roads. Nos. 2, 3, 4, and 5 are shipped "knocked down;" to economize space in shipment are put together easily by accompanying bolts, etc. They occupy from two to five times as many cubic feet when erected.

All charges included, we suppose, No. 3 Evaporator would compare pretty closely with an £85 sirocco in cost (about R1,200 laid down in Colombo) so that the work done by each could be fairly compared. The other details given regarding No. 3 are that its surface drying capacity in square feet is equal to 300; number of trays 45; capacity for drying in pounds 3.000 (which we take to mean that it can accommodate 3,000 lb. to be dried at one time?); consumption of coal 200 lb. As regards drying capacity, there is a note to this effect:—

For purposes of calculation capacity for drying is based upon actual performances as claimed in descriptive Treatise. One bushel of apples—(say) 60 lb. Allowance must be made for excess of moisture as compared with tea, coffee, cacao, spices, indigo, &c.

The great merit claimed for the evaporator is that its trays are not superimposed, and therefore the hot steam from the lower trays will not sodden and spoil the tea on the upper trays. But our observation has not led us to conclude that any special injury is inflicted on tea when dried on a series of trays one above the other. The trays are constantly shifted, until the lower one gets to the top. It certainly seems, however, as if it must be a great improvement that the passage of steam from the lower to the upper trays should be avoided, but we repeat that the proper proof of the value of the American machine is a practical trial. Of such trial we ought soon to learn, either as conducted here or at the Jorehaut Assam Company's head factory at "Cinnamara," where Mr. Jackson's new drier was recently tried and where a No. 3 evaporator has been placed. Meanwhile, Mr. Hollingsworth, an experienced tea planter states:—

Reverting to the value of the "American," as a tea dryer, I would say that I have personally experimented upon its capabilities for this special purpose with entire success and satisfaction, having procured the leaf from a plantation growing tea in South Carolina.

In the pamphlet allusion is made to the

Great uniformity of appliances and the monotonous adherence to past theories in the construction of tea driers.

The fact is, as our readers are aware, that tea driers have been constructed on principles so opposite as the tray system and Gibbs & Barry's inclined cylinder, the latter somewhat resembling the tube through which the trays of the evaporator pass. From the pamphlet we quote as follows:—

Freedom from scorching, or discoloration of tips.

Economy in cost, labor, fuel and heat.

Its simplicity, durability and portability.

Immunity from fire when used in "Cutcha" buildings.

Its adaptability for burning all kinds of fuel, viz: coal, coke, charcoal, bamboo wood, ekara, kagri, ooloo &c.

Absence of lengthy smoke-stacks and consequent safety in cyclones, hurricanes, or earthquakes.

That its use dispenses with brick-making, lime, masons, carpenters and wood cutters' expenses, as also the need of chulas or dholes, and nearly so, the demand for salonies &c.

Besides the qualities thus indicated, the claims are :—

To the owners of small gardens, as a rule unable to afford the costly and cumbersome machines in present use, the American offers unqualified inducements from the extreme lowness of its price, which places it within reach of all, in one size or other.

To large concerns, its many excellent qualities, aside from cost, find appreciation particularly in the value of the American as a preserver of aroma and pungency, for by the Inclined Flue Evaporating Trunk, which our patents especially protect, we have most effectually overcome those highly objectionable features which depreciate the market value of all products especially tea, when subjected to a drying process where the steam or vapor from the lower trays necessarily comes in contact with the ones previously entered.

However excellent they may hitherto have appeared, the fact remains that in all that class of driers having a series of trays one above the other, the direct tendency and practical result effectually combine to extract and dissipate the flavor and strength almost as effectually as the same would be accomplished in drawing or steeping the leaf in hot water.

The aroma in tea is due to the volatile essential oil contained therein, which is easily expelled, especially under so favorable a combination of circumstances heretofore unwittingly employed, leaving a preponderance of Tannin (Tannic Acid) with diminished flavor and increased acerbity. In the green leaf manipulation this defective old proces is alike disastrous and destructive of the very elements that enter as factors in flavor, pungency, or strength and which result in low prices, lessened profits and consequent meagre dividends.

By the mechanical devices, and the galvanized wire gauze cloth employed in the American Evaporator, we have reduced to a minimum all risks of discoloration of tips or leaf which arise from the chemical action of the Tannic Acid on the iron. This burning turns leaf blackish and tea bluish. Retention of flavour and enhanced pungency are secured by our system of direct action of dry heat which combines brisk or high firing with absence of all scorching or burning and the stoppage of undue fermentation is hereby insured as effectually as panning would do it.

Ordinary coolies and workmen can, it is said, erect the machine, and one cooly of average intelligence can work one or even two ! It will not only prepare tea, but also

Coffee cinchona, sago, beetlenut, spices, fish, prawns, bumlow muchee, curry-stuffs &c.

So far about tea, but, when coffee is reached, Mr. Hollingsworth or somebody else gets out of his depth and writes great nonsense about drying in the pulp being so much better than pulping, while the discoveries are made that coffee is indigenous to Ceylon, India and Brazil and that a good substitute for Mocha coffee is obtained by gathering the small berries from the tips of branches ! But we must quote what is said of coffee and its curing :—

The value of a universal economic and scientific process in the manipulation of the succulent coffee bean, by the de-hydrating process, instead of the ruinous pulping method now practiced, can scarcely be correctly estimated without apparent extravagance of statement.

In this vast industry, especially pertinent (owing to climatic conditions) to India and Brazil, the monetary value of a better process cannot be over estimated. It contemplates and secures for the raw bean a marked and radical improvement in its relative analytic constitution ; in cellulose and Coffeine and by the process of ripening and absorption, the valuable properties of the succulent, pulp the marked development of aromatic oil, Coffeone which are the prime factors of commercial value in all coffee, are greatly enhanced. These qualities are at once apparent in the roasted article, from the bean prepared by this method, and impart to the beverage that bland, mellow, aroma now almost foreign to the best article as prepared by present methods, unless partially secured at prohibitory expense and loss, by several years aging of the raw bean. In brief, the advantage noted constitute one of the greatest of economic and sanitary problems of the present day.

Our process, as embodied in the American Evaporator, and which has so effectually and satisfactorily revolutionized former methods of dissicating fruits and vegetables of all kinds, and has proven so eminently satisfactory in tea and coffee, that we confidently present its merits and utilization in said industries generally, with assurance that it will in the near future furnish the line of demarkation between erroneous and correct methods in both.

The hardy, robust and prolific Liberian coffee tree, adapted to low altitudes, is proving a formidable and successful rival to the species which heretofore claimed almost exclusive attention. This is particularly applicable to the many situations unsuited to the Arabian.

The coffees indigenous to Ceylon, India and Brazil are highly aromatic and finely flavored, and are susceptible of rivaling Mocha, and from said sources, but under an assumed name, practically speaking, our acquaintance with so called Mocha is obtained. The careful grading and assorting of the small berries obtained from the tips of Brazilian and Indian plantations furnish the world with all the Mocha the trade demands; while in truth, the annual production of Arabian Mocha would not furnish the Rio de Janeiro market with an average daily sale. Starting with so promising a product, we desire to urge upon planters the importance of supplying the favorable conditions in the curing that give to the Mocha of Arabia by reason of its dry rainless season, its peculiar merit and commercial value.

After all is said and done, we suppose coffee dried in the cherry really retains additional flavour, but the difficulty and expense of subsequent cleaning are prohibitory.

In conclusion, we can but repeat that we hope soon to see a practical trial of the American Fruit Evaporator as a Tea Drier.

TEA IN CEYLON.

(*Home and Colonial Mail*, Oct. 24th.)

The rapid development of tea cultivation in Ceylon is creating both attention and surprise at home. The energetic way in which planters who, having suffered losses in connection with coffee, have adopted a new enterprise, is appreciated by all who admire perseverance and pluck. They might, had they been content to accept the situation without an endeavour to retrieve it, have seen ruin staring them in the face. Indeed, too many of them unable from want of funds to make a new departure, had to accept the inevitable. Others have but failed in one direction to attempt success in another. Undoubtedly Ceylon is likely to prove a formidable rival to India as a tea-producing country. The island is in many respects admirably suited to the growth of tea, and it has advantages in the way of transport facilities, which are not possessed in India. A Ceylon planter, now in London, has given us a few particulars of his experience in the Maskeliya Valley and other districts. Our informant, who was formerly a coffee planter, until he was nearly ruined by the adverse influences which came upon the island, has transferred his affections and the balance of his capital to tea. He may be over sanguine, but his views are borne out by others whose previous experiences have taught them moderation. The gentleman to whom we refer has 480 acres under tea, being about two-thirds of the acreage of two coffee estates, the produce of which he can "lay down" in London at 9d. per lb., although he has but crude arrangements as yet for manufacture. With suitable plant and machinery he thinks he can place his tea on the London market at a cost of 7d. per lb. The return per acre ranks of course according to soil and situation, but we were told of tea estates which were estimated to yield from 200lb. to 1,000lb. per acre, viz., 200lb. per acre from three-year-old trees, and 1,000lb. per acre from six-year-old trees, the latter being a return so remarkable that we can only hope our informant's anticipations and his figures are blended judiciously. A return equal to 700lb. per acre has, our informant tells us, been already realized. Soil already used for coffee and by many regarded as unsuited to tea appears to answer admirably, and thus some planters who have a portion of an estate in coffee are able to plant the remainder in tea. Under these circumstances it is evident

that a big tea "boom" may be expected from Ceylon; and it is no wonder that the attention of Mincing Lane is directed thitherward. The manufacturers of tea machinery will doubtless pay heed to the requirements of Ceylon planters, who are now on the look out for suitable machinery. The rivalry of Ceylon is an additional reason, were any required, why planters in India should devote themselves to a study of the economic side of the question of manufacture.

(*Home and Colonial Mail*, Oct. 31st.)

(*To the Editor of the Home and Colonial Mail.*)

Sir,—In your Planters' Supplement last week, I notice that you appear to think the estimated yield mentioned to you by a Ceylon planter of from 200 lb. to 1,000 lb. per acre, as sufficiently remarkable to be almost classed with the impossible.

I notice also that an Indian paper, received by last mail, commenting in a leading article upon Ceylon production, expresses this doubt very forcibly, even at the reduced figure of 800 lb., thus: "Nowhere can our best and most experienced planters turn out anything like this (10 maunds per acre) from the best virgin soils put under tea in Assam."

There appears to me from all this a curious absence of planters' gossip in editorial chambers. What Sadiya Road planter does not remember the old days when Bisakopie, under the management of the late Mr. Bone, and long previous to the formation of the present Doom Dooma Company, yielded 12 maunds or 960 to 980 lb. per acre and over, from a considerable area, and off *China* bushes, too! This is quite a tradition now. Again, who does not among old Jorehaut planters remember a garden of indigenous tea, which produced 12½ maunds of tea per acre, which garden is the parent now of numbers of other, its seed having reached the highest figure on record, owing to its wellknown splendid yield. Though these yields. I admit, are remarkable, they *have* been proved possible in Assam.—I enclose my card, TRUMP.

ENEMIES TO SUGAR IN QUEENSLAND.—I noticed a number of Minah birds from India, which have been purchased, and will be let loose to aid in the destruction of locusts, which have done so much injury to the Victoria and Hamleigh plantations in this district. A number of mongoose have also been imported, and have already been set at liberty, it being hoped, by this means, to lessen the loss which occurs through injury done to the cane by field rats.—*Cor., Sydney Mail.*

THE TRADE IN GINSENG: CHINA REACTING ON VIRGINIA.—One of the most curious instances of how matters, apparently the most remote, react upon each other, is (says the New York *Hour*) found in the distress occasioned in the rural population of West Virginia by the Franco-Chinese war, owing to the fact that the market for ginseng is closed, or dulled, and the price has fallen by a large percentage. The mountain people of the Alleghany highlands from Pensylvania to Tennessee have long been accustomed, in early Spring and late Fall, to dig the root of this plant, and prepare it for sale for scalding and cleaning. It was then sold to the country merchants, and served as almost the only means by which the rude dwellers in the interior of the mountains got any ready money or its equivalents in the few "store-goods" they consumed. Twenty-five years and more ago, the root was worth only about thirty cents a pound, and every little trading centre would export four or five thousand pounds annually. Latterly, however, the mountains became so depleted that the root rose to a dollar a pound in value. With the exception of a trifle, used in our pharmacy, the whole demand for this herb comes from the Chinese, in whose medicinal arts it stands almost first in importance. It is not only regarded as a panacea, and prepared for use in nearly every way a physician can contrive; but takes a superstitious rank, chiefly through the fancied re-emblances seen in the gnarled pieces of root to human faces, and a variety of other forms, earthly and celestial.

CINCHONA PLANTING IN GUATEMALA.—We are glad to hear of the welfare of Mr. W. J. Forsyth, formerly planter here, now in Central America. Mr. Forsyth has been travelling about a great deal. The cinchona seed he carried from Ceylon and Southern India has "come up very successfully all over the country."

DAMAGED PEPPER.—At the beginning of this month 2,000 bags of pepper (about 240,000 lb. were sold in London by public auction. There is nothing wonderful, perhaps, in this, but it is a fact that the pepper, which had been recovered from a recent extensive fire at New Crane Wharf, was saturated with Thames water, which at this point in the river's course is not precisely *aqua pura*, consisting as it does very largely of sewage. Consumers of pepper—possibly dealers, too—should take for their motto for some little time to come, "Caution, and plenty of it."—*Druggist.*

A SYNDICATE has been formed in London to start a quinine manufactory in the old Cullai Iron Works at Calicut, and has sent out a manager to begin operations This gentleman is commissioned to make experiments as to the price at which quinine and the allied alkaloids can be produced in India; and if there is a fair prospect of success, I understand that money will be forthcoming for establishing the industry on a large scale. This would be a great benefit to cinchona growers, as they would have a local market for the cheaper varieties of their bark which it hardly pays to ship to England, or even to Madras, at present prices.—*Wynaad Cor., Madras Mail.*

A CHECK TO ADULTERATION.—The West Indian Body, always on the alert for opportunities to protect the interests of the colonies, have asked the Board of Trade to issue notices to the grocers to mark their packages "cane," "beet," or "mixed," under the Sale of Food and Drugs Act, so that when a person applies for cane-sugar some security shall be given that it will be supplied It is well-known that preserves and jams can only be properly made with cane-sugar, and, of course, the difficulty arises as to whether the article supplied is of the right quality—that quality being determined, of course, by origin. The Board of Trade have referred the matter to the Local Government Board under whose supervision the administration of the Sale of Food Act rests. It is evident, however, that something will be done in the direction contemplated.—*Colonies and India.* [Why not have coffee treated similarly in reference to percentage of chicory? —ED.]

THE LABOUR QUESTION, says the North Queensland correspondent of the *Melbourne Argus*, is still the harassing problem of the planter Several mills will lose a third of their islanders before the crushing season is completed. As no large number of kanakas are now arriving—it being no uncommon occurrence for a vessel to return almost empty after a cruise of months—this will make things awkward for the manufacturer, but the pinch will not be really felt until another season comes round, for by then another third of the "boys" will have left, and by the year after the remaining third will be gone. The Government suggest as a remedy the introduction of cheap Europeans from Germany, Denmark, Sweden, &c., and offer to bring these over upon the planter paying £1 per head, but the whole of the selecting and initiatory expenses and business are to be done by the planter's private agent—a plan which will cause, in all probability, considerable confusion. The odd part of this immigration scheme is that this proposal to flood the country with cheap (10s per week) European labourers, who will, when their term of agreement expires, most certainly compete with the colonist, emanates from the so called liberal party who were raised to power by the working man vote. The planters are quite willing to give the scheme a trial, and have been holding meetings to arrange as to how the matter can be speedily brought into working order.—*Australasian.*

A SPONGE, five feet seven inches in circumference, and weighing six and-a-half pounds, is on exhibition at Watertown, New York. It will hold twenty-four gallons of water, and is valued at $25. The sponge came from the Bahama Islands.—*Indian Agriculturist.*

INDIA: COFFEE CROP.—It is reported that this season's coffee crop is a great success in comparison with that of the previous year. Picking is busily carried on in all the estates, but we regret to observe that the planters are seriously inconvenienced by the stoppage of the mills at Colachel, seeing that those who require their coffee cured, have to send the article either to Quilon or Tuticorin.—*Western Stor.*
